The loop-colostomy technique (Fig. 37-3) is preferred over the end-colostomy technique because it is easier and quicker to establish and to reverse later.20,21 Concerns about incomplete diversion of feces do not apply to a loop colostomy in horses because gravity, combined with correct construction of the stoma, prevents passage of feces into the distal small colon and rectum.20-22

A loop colostomy can be created in a left high flank, a left low flank, or a ventral midline incision, and all have advantages and disadvantages (Table 37-1). A single-incision colostomy involves placing the stoma in the same incision used to explore the abdomen and prepare the colon loop, whereas a double-incision colostomy involves a separate flank incision for the stoma.20 Exploration of the abdomen through the ventral midline is necessary if the horse has a surgical colic that preceded the tear,21 if intra-abdominal repair of the tear is considered feasible,14,23 or if the surgeon elects to empty the large and small colons to reduce stress on the colostomy. Colostomy placement in the anesthetized horse has the following disadvantages: (1) accurate placement of the stoma is difficult because muscle layers shift and landmarks become distorted in the recumbent horse compared with the standing horse, (2) it is expensive, and (3) dehiscence of the stoma is a risk of rough anesthetic recovery.20,21 Marking the selected site on the skin with a pen or suture preoperatively while the horse is standing does not obviate the first problem, because the muscle layers disrupt the attachments when the horse stands, even when the skin incision is accurately located. With single-incision colostomies, incorporation of the colostomy in the abdominal closure weakens the body wall repair and makes the ventrally placed stomas, such as the low flank and ventral midline placements, prone to prolapse and herniation.20

With the double-incision technique, the stoma is placed in a snug low flank incision so that it is surrounded by intact body wall and the risks of prolapse and herniation are reduced.20

With the double-incision technique, a high flank incision is used to prepare the colon loop and guide it into a separate low flank incision, midway between the flank fold (just rostral to the stifle) and the costal arch, and at the same level as the fold20 (Figs. 37-4 and 37-5). The distal incision is approximately 8 cm long and extends through all layers, and deep dissection is guided by a hand through the high flank incision. It is angled dorsally at its caudal end by 20 to 30 degrees. Small transverse incisions are made in muscles and fascia to eliminate constricting bands that could restrict fecal passage. The stoma should not be large and loose fitting, because this would reduce the risk of stomal obstruction but predispose to the more serious complications of prolapse and herniation.20

If general anesthesia and ventral midline celiotomy are required, this stage of the surgery should be completed as needed to correct the problem. The horse is subsequently placed in lateral recumbency to complete the colostomy in a separate flank incision.21 This somewhat reduces problems from shifting muscle layers when the horse stands. A heavy retrieval suture (size 2 nylon) is placed on the antimesenteric band of the prepared loop of small colon before closing the midline incision, so that only a small flank incision is

*Information applies to both loop and end colostomies.
required to form the colostomy. The ends of the retrieval suture are placed on a long needle and brought through the body wall at the site marked for the colostomy. Unlike with the double-incision technique, the surgeon must bring the prepared loop of small colon through the small incision at the site of the stoma, without being able to direct the loop through a separate larger incision.

Regardless of the approach, the stoma is made in a segment of small colon at least 1 m from the rectum so that the small colon can be easily exteriorized for colostomy reversal. This segment of small colon is folded to form a loop, and the two arms of the loop are sutured together with an absorbable material in a continuous Lembert pattern for 8 to 10 cm, midway between the mesenteric and antimesenteric teniae. This suture line is brought closer to the mesentery at the folded end of colon to turn the antimesenteric tenia along the outer edge of the fold. The adhesion along this suture line creates a more complete mucosal separation between the proximal and distal segments of small colon and thereby enhances complete fecal diversion. The adhesion can also stabilize the loop within the body wall, reducing the risk of prolapse. The prepared loop of small colon is subsequently inserted into the flank incision so that the proximal loop is slightly ventral to the distal loop and the antimesenteric tenia projects beyond the skin by at least 3 cm.

Regardless of the approach, the stoma is made in a segment of small colon at least 1 m from the rectum so that the small colon can be easily exteriorized for colostomy reversal. This segment of small colon is folded to form a loop, and the two arms of the loop are sutured together with an absorbable material in a continuous Lembert pattern for 8 to 10 cm, midway between the mesenteric and antimesenteric teniae. This suture line is brought closer to the mesentery at the folded end of colon to turn the antimesenteric tenia along the outer edge of the fold. The adhesion along this suture line creates a more complete mucosal separation between the proximal and distal segments of small colon and thereby enhances complete fecal diversion. The adhesion can also stabilize the loop within the body wall, reducing the risk of prolapse. The prepared loop of small colon is subsequently inserted into the flank incision so that the proximal loop is slightly ventral to the distal loop and the antimesenteric tenia projects beyond the skin by at least 3 cm.

Figure 37-4. Loop colostomy placed in the low flank by a double-incision technique as a standing procedure 2 days earlier. Congestion in the mucosal shelf separating the proximal and distal parts of the small colon is typical for this stage.

Figure 37-5. Loop colostomy placed in the low flank by a double-incision technique as a standing procedure, 60 days later (horse is not that shown in Fig. 37-4). The stoma is mature and healed to the surrounding skin; the mucosal shelf is evident as a small bulge in its midpoint.

The seromuscular layer of the colon is sutured to the abdominal muscles and fascia using several interrupted sutures of 0 or 2-0 absorbable material, taking care not to puncture or occlude mesenteric vessels. To form the stoma, an 8-cm incision is made along the exposed antimesenteric tenia of the colon, and the cut edges are folded back and sutured to the skin with simple-interrupted sutures of 2-0 nylon or polypropylene (see Fig. 37-3). The opening thus formed is approximately the same size as the small colon lumen (see Fig. 37-5). Because fecal balls are eliminated individually as they pass through the small colon, without being stored to form piles, as in the rectum, the risk of obstruction is low.

An alternative method for loop colostomy is to suture the colon loop to skin only and to detach and oversew the stoma at 14 days. The abdominal muscle layers and skin are then closed. Disadvantages of this method are that such an attachment may allow peristomal herniation and that the rectal tear is unlikely to heal in 14 days.

END COLOSTOMY

Some surgeons prefer an end colostomy because of the concern about incomplete fecal diversion with the loop colostomy method, a concern most likely carried over from experiences with the supine human patient. However, the loop colostomy method does allow complete fecal diversion, because gravity causes fecal balls to drop away from the stoma rather than turn into the distal segment. For the end colostomy, the colon is transected, the distal segment is closed by the Parker-Kerr method, and the proximal end is incorporated into the body wall as for the loop colostomy. The distal segment tends to atrophy, so its diameter and length may become reduced by 50%. This makes colostomy reversal by future anastomosis difficult and causes anastomotic impactions and dehiscence.

AFTERCARE FOR COLOSTOMY

Antibiotics and laxatives (mineral oil, 2 to 4 L/450 kg, and magnesium sulfate, 1 g/kg) are continued for 3 to 5 days. Horses are held off feed or fed grass and alfalfa hay at half the usual amounts for the first 2 to 3 days after the colostomy is established, and petrolatum-based ointment is applied to the skin around the stoma to protect it from scalding. A cradle is applied because most horses have a tendency to mutilate the colostomy.
When the loop colostomy is created, the mucosal protrusion of the stoma becomes markedly congested over the first 5 to 7 days after surgery (see Fig. 37-4) and slowly sloughs, to be replaced with healthy tissue (see Fig. 37-5). Considerable ventral edema can develop, but it resolves with time.

With the loop colostomy, it is possible to exercise the distal part of the small colon and prevent the atrophy that complicates anastomoses with the end colostomy. When the tear has started to granulate, usually after 5 to 7 days, the distal loop of the small colon and the rectum are flushed daily in normograde fashion with approximately 20 L of warm water through a garden hose.

**COLOSTOMY REVERSAL**

For colostomy reversal, usually 6 weeks or more after the colostomy, the horse is anesthetized in right lateral recumbency, the stoma is resected en bloc, and a colonic anastomosis is performed through the resulting flank incision. Even if the colon is not penetrated during dissection, incisional infection is a common complication of stomal resection. Penrose drains should be inserted in deeper tissue layers and left in place for approximately 3 days.

For anastomosis, the distal segment is transected along a more acute mesenteric angle than the proximal segment to correct for a slight reduction in distal diameter. A single layer of interrupted Lembert sutures with 3-0 polydioxanone (PDS) is used for anastomosis, but other methods also are suitable. The stapled side-to-side technique is likely to become impacted despite the large stoma. The postoperative feeding, antibiotic, and laxative regimens are similar to those used after the colostomy procedure.

**COMPLICATIONS OF COLOSTOMY**

Complications of colostomy are dehiscence, abscession, peristomal herniation, prolapse, prolapse with rupture of mesenteric vessels, infarction, rupture of the colostomy, spontaneous closure, and stomal obstruction, as well as anastomotic impaction and dehiscence after reversal. Herniation and prolapse have been attributed to ventral placement of the stoma and to a stoma that is too large. There is a tendency to make the stoma large to prevent stomal obstruction, although stomal obstruction is rare, probably because fecal balls are voided individually.

**CHOICE OF DIVERTING PROCEDURE**

The choice between colostomy and temporary indwelling rectal liner for definitive treatment of a rectal tear is influenced largely by cost and by the surgeon’s preference, because the two methods have comparable success rates. The outcome is most likely to be determined by complications of the tear that developed before application of the diverting procedure. Colostomy does have inherent, life-threatening risks and is more expensive because it is a two-stage procedure. A potential advantage of colostomy is that it allows the surgeon more complete control over the duration of fecal diversion, which could be important if healing of the tear is delayed. Colostomy is preferred for large tears, small horses, and a tear that is too far proximal to accommodate a rectal liner.

The most difficult decision is whether a fecal diversion procedure is required at all, because some horses with grade III rectal tears can make a full recovery without surgery (see later). Although few criteria can be used to guide treatment selection, the decision to use diverting procedures must be made quickly to derive full benefit, preferably within 12 hours after the tear occurred. Because the cost of diverting procedures can be considerable, many owners may opt for less expensive procedures, such as direct suturing or medical treatment combined with repeated manual rectal evacuation.

**Suture Repair**

Suture repair can promote healing and prevent progression of a grade III tear to a grade IV tear. It should be combined with a diverting procedure if there is any concern about the integrity of the repair, but this is not always necessary and can be precluded for economic reasons. The surgery is easiest to accomplish on a thin horse with a tear that is fresh, clean, and close to the anus. Long-handled instruments with pistol grips and a 60-cm-long expandable rectal speculum or “cage” have been developed to facilitate suture repair of rectal tears in horses. The anal sphincter can be incised to improve access to a rectal tear and to ease defecation afterward. A large wound of long duration can be partly closed or left open to allow drainage, and the defect can be packed with antiseptic-soaked gauze to prevent fecal impaction and dissection. A grade IV tear has been repaired successfully with the TA-90 Premium stapling instrument (United States Surgical Corp, Norwalk, Conn), because the tear created a pneumoperitoneum and equilibration of pressure across the rectal wall that allowed it to be drawn through the anus. If the rectal tear is not accessible through the anus, it can be prolapsed through it from a caudal ventral midline laparotomy or repaired through an antimesenteric enterotomy from a ventral midline approach. Suture repair under laparoscopic control appears to be a promising method for the future, but the instruments may be too short in some cases.

A technique for nonvisual direct suturing has been reported to have favorable results and is a simple and inexpensive standing procedure. If the tail is elevated and the anal sphincter relaxed from the caudal epidural anesthesia, the rectum fills with air and the surgeon has
more room in which to manipulate the needle. This ballooning effect is poor in rectums with grade IV tears because of the equilibration between intra-abdominal and atmospheric pressure, and it diminishes in grade III tears if surgery is prolonged. Fecal material is digitally removed from the rectum and distal small colon, and the defect and lumen walls are cleaned carefully and thoroughly by wiping with moistened 4×4 gauze sponges. If the tear does not involve the full thickness of the wall, gentle gravity lavage can be used to clean the tear. In a grade IV tear, the severity of peritoneal contamination determines whether a repair should be attempted.

The left hand is used for tears on the right side, and vice versa, and gloves are not worn. The preferred suture is size 5 Dacron (Deknatel Inc, Fall River, Mass), 100 to 150 cm long, with a 6- to 8-cm, half-circle cutting or trocar point needle placed in the middle of the suture. A cruciate or simple-interrupted pattern is used. With both ends of the suture outside the rectum, the needle is manually advanced to the tear. The first bite is placed in the center of the caudal edge of the tear, holding the needle with the thumb and first two fingers. The needle is inserted approximately 1.5 cm from the edge of the wound and guided into the defect subserosally by the second or third finger (Fig. 37-7). The needle is pulled through the tissue, again grasped with the thumb and first two fingers, and then placed in the center of the cranial edge. This bite begins subserosally within the defect and exits 1.5 cm from the edge. The third finger is used to guide the exit point and press the tissue onto the needle. The needle is subsequently brought out the rectum, leaving a single strand of suture in the tear with the other end extending 10 to 15 cm distal to the anal sphincter. The suture is then clamped with a hemostat between the needle and the point of exit from the tear and the needle remains threaded on the proximal half of the suture. An assistant holds the clamped suture to one side to close the defect into a transverse plane, and the needle is carried into the rectum. The suture is then passed through both cranial and caudal edges of the defect in one bite using digital manipulation as before, and finally the needle is brought out the rectum. The hemostat is released and the needle end of the suture is drawn through to form a cruciate suture. The knots are tied outside the rectum and pushed inside with one hand while tension is maintained on the suture with the other hand. Additional throws are placed to secure the knot.

Traction on the first suture should convert the tear to a transverse orientation, which facilitates placement of about two or three more sutures on each side of the first. Care must be taken to prevent lumen reduction by the closed defect as its edges turn into the lumen. The suture ends are cut long to facilitate their removal, but if the feces cannot be kept soft, the ends should be cut short so that they do not get pulled out by fecal balls. The sutures are checked at 24- to 48-hour intervals, and any suture that feels slack from loosening or reduction of edema is replaced. The sutures are removed in 12 to 14 days.

Nonvisual direct suturing may not be easily mastered and can require extensive practice. It is a useful technique for tears involving half or less of the rectal circumference, and for tears that have very small perforations of the serosa, but it is recommended as an adjunct and not as a primary treatment for grade IV tears.

The 45-cm-long Deschamps needle (Eickemeyer, Tuttlingen, Germany), which is made in both right- and left-handed configurations (Fig. 37-8), is ideal for one-handed suturing in a deep recess (Fig. 37-9) and has been used successfully for standing repair through the anus. The needle tip should be sharp. Both chromic catgut and polyglycolic acid suture have been used. A right-handed surgeon guides the Deschamps needle rectally to the wound, with the left hand serving as protection and the right hand turning the handle (see Fig. 37-9). The caudal end of the perforation is grasped with the index finger and thumb of the left hand, and the needle is guided through the mucosa, muscularis, and serosa (if present), about 1 cm away from the wound edge. The ventral wound edge is penetrated, the suture is removed from the eye of the needle, and a surgical knot placed outside the rectum is pushed in with the left hand. An assistant pulls the ends of the first knot through the anus to stabilize the repair and bring the wound edges together. Additional single sutures are placed from caudal to cranial, 1 cm apart, so that the wound closes to form a ridge (see Fig. 37-9). If the suture bites exceed 1.5 cm from the wound’s edge, the rectum becomes too narrow.

The preferred suture for repair of rectal tears should be long, have low memory, resist stretching, and resist fecal digestion. Small suture tends to cut through the friable tissue edges, and catgut tends to stretch. Continuous suture patterns are not recommended because they reduce the lumen diameter, which predisposes to impaction and dehiscence. A complete pellet ration can be fed after a 2-day fasting period to produce a small fecal bulk, and mineral oil can be used to soften feces. Mineral oil is not used if the repair of a grade IV tear is tenuous, because it could leak into the abdomen.

Figure 37-7. Diagram showing the first bite of the nonvisual direct suturing technique being placed in the center of the caudal edge of the tear. The needle, held with the thumb and first two fingers, is inserted approximately 1.5 cm from the edge of the wound and guided into the defect subserosally by the second or third finger. (Drawn from Eastman TG, Taylor TS, Hooper RN, Hague, BA: Treatment of grade 3 rectal tears in horses by direct suturing per rectum, Equine Vet Educ 2000;12:63, with permission.)
Nonsurgical Treatment
Grade I and II tears rarely require surgical treatment and grade I tears respond in most cases to antibiotics (e.g., trimethoprim sulfonamide, 20 mg/kg PO every 12 hours), and flunixin meglumine (1.1 mg/kg IV or PO, every 12 hours), mineral oil (1 gallon via nasogastric tube every 24 hours), and dietary changes such as bran mashes, moistened pellets, or grass to reduce fecal volume and soften the consistency. If all or a significant portion of the submucosa layer remains intact, grade I tears should heal with medical management without complications.

Although grade III tears usually require surgical treatment, medical management can be successful and is considerably less expensive than surgical methods. In one report, six of eight horses with grade IIIb rectal tears were treated successfully with broad-spectrum antibiotics (penicillin, gentamicin, and metronidazole) and nonsteroidal anti-inflammatory agents, maintenance of soft feces with a diet of grass and bran mashes and daily administration of mineral oil by nasogastric tube, and daily manual removal of feces from the rectum after sedation and epidural anesthesia. All horses developed septic peritonitis, and three of the six survivors developed a rectal diverticulum in the tear, without any apparent clinical effects. The authors felt that manual evacuation of feces should be performed only if the tear became impacted, and the procedure should be conducted with extreme care.

In another report on successful medical treatment of four horses with grade IIIb tears, the authors recommended frequent manual evacuation of feces on a daily basis. Frequency of manual evacuation decreased from every 1 to 2 hours to every 6 to 8 hours by the 4th and 5th day, and the evacuations were discontinued between 9 and 21 days. The underlying principle in this approach was to eliminate the storage function of the rectum and thereby eliminate impaction of feces into the tear. Although this treatment is simpler to perform than bypass procedures, it is labor intensive and does require repeated epiduals through an epidural catheter.

Full-thickness tears into the retroperitoneal space may be treated with manual evacuation of feces, antimicrobial therapy, fecal softener, and packing with gauze soaked in antiseptic solution until the defect fills with granulation tissue. Perirectal abscesses that follow this treatment can be drained into the rectum or perianally with a chest trocar. Ventral tears in mares can be drained through the dorsal vaginal wall. As with any method of treatment, peritonitis from the tear can be treated by peritoneal lavage, although this approach was not used in many cases reported in the literature.
Prognosis for Rectal Tears

Complications of grade III rectal tears are extensive and include cellulitis, abscess formation, severe toxemia, peritonitis, laminitis, and recurrent intestinal obstruction from adhesions. The time required for healing of rectal tears varies from 2 to several weeks. Most tears heal with little residual damage, but some can form a stricture, a diverticulum, or perirectal abscessation. Such abscesses must be drained into the rectum by finger puncture and can delay colostomy reversal for up to 60 days. Grade III and IV tears can heal to form a mucosal or submucosal hernia that can subsequently become impacted with feces, and a grade IV tear can form a rectoperitoneal fistula.

In one survey of 85 horses, conservative management of 15 horses with grade I tears yielded a 93% survival rate. Grade IIIa rectal tears had a 70% survival rate in this study (16 of 23 horses), and grade IIIb rectal tears had a 69% survival (9 of 13), compared with a 44% survival rate in a previous study. Survival for grade IV tears was 2 of 31 horses.

Nonvisual direct suturing of rectal tears in the horse has a higher success rate than that reported for other techniques. In one study, 75% (15 of 20) of horses treated by this technique survived until discharge. Eighty-one percent of horses (9 of 16) with grade IIIa tears and 50% of horses (2 of 4) with grade IIIb tears were discharged alive after suture repair. The sutures did not hold in three horses, and the tears converted to grade IV at 1 to 7 days after surgery, and one horse died of peritonitis from an unidentified grade IV tear oral to the sutured grade III tear. Long-term follow-up was available for 10 of 15 survivors (66%), all of which survived at least 6 months. Horses discharged alive were hospitalized an average of 15 days (range, 9 to 24 days).

Rectal Prolapse

Causes of rectal prolapse are straining from diarrhea, dystocia, intestinal parasitism, colic, proctitis, rectal tumor, and rectal foreign body. In many cases, a cause cannot be identified. The condition is more common in females than in males and may affect any age group.

Classification

In a type I rectal prolapse, only the rectal mucosa and submucosa project through the anus, sometimes more so on one side than on the other. A type II lesion represents a complete prolapse of the full thickness of all or part of the rectal ampulla. Type I and II prolapses are the most common. In a type III prolapse, a variable amount of small colon intussuscepts into the rectum in addition to a type II prolapse. In a type IV prolapse (Fig. 37-10), the peritoneal rectum and a variable length of the small colon form an intussusception through the anus. This type of prolapse is seen with dystocia in mares.

Prognosis for Rectal Tears

Complications of grade III rectal tears are extensive and include cellulitis, abscess formation, severe toxemia, peritonitis, laminitis, and recurrent intestinal obstruction from adhesions. The time required for healing of rectal tears varies from 2 to several weeks. Most tears heal with little residual damage, but some can form a stricture, a diverticulum, or perirectal abscessation. Such abscesses must be drained into the rectum by finger puncture and can delay colostomy reversal for up to 60 days. Grade III and IV tears can heal to form a mucosal or submucosal hernia that can subsequently become impacted with feces, and a grade IV tear can form a rectoperitoneal fistula.

In one survey of 85 horses, conservative management of 15 horses with grade I tears yielded a 93% survival rate. Grade IIIa rectal tears had a 70% survival rate in this study (16 of 23 horses), and grade IIIb rectal tears had a 69% survival (9 of 13), compared with a 44% survival rate in a previous study. Survival for grade IV tears was 2 of 31 horses.

Nonvisual direct suturing of rectal tears in the horse has a higher success rate than that reported for other techniques. In one study, 75% (15 of 20) of horses treated by this technique survived until discharge. Eighty-one percent of horses (9 of 16) with grade IIIa tears and 50% of horses (2 of 4) with grade IIIb tears were discharged alive after suture repair. The sutures did not hold in three horses, and the tears converted to grade IV at 1 to 7 days after surgery, and one horse died of peritonitis from an unidentified grade IV tear oral to the sutured grade III tear. Long-term follow-up was available for 10 of 15 survivors (66%), all of which survived at least 6 months. Horses discharged alive were hospitalized an average of 15 days (range, 9 to 24 days).

Rectal Prolapse

Causes of rectal prolapse are straining from diarrhea, dystocia, intestinal parasitism, colic, proctitis, rectal tumor, and rectal foreign body. In many cases, a cause cannot be identified. The condition is more common in females than in males and may affect any age group.

Classification

In a type I rectal prolapse, only the rectal mucosa and submucosa project through the anus, sometimes more so on one side than on the other. A type II lesion represents a complete prolapse of the full thickness of all or part of the rectal ampulla. Type I and II prolapses are the most common. In a type III prolapse, a variable amount of small colon intussuscepts into the rectum in addition to a type II prolapse. In a type IV prolapse (Fig. 37-10), the peritoneal rectum and a variable length of the small colon form an intussusception through the anus. This type of prolapse is seen with dystocia in mares.

Figure 37-9. Method of inserting the Deschamps needle into the rectum and guiding it to the tear while protecting the tissues with the right hand. The close-up in the middle shows how the Deschamps needle grasps both sides of the tear and pulls the suture through it as well. The lower diagrams show the suture placement for a grade IV tear.

a, serosa; b, muscularis; c, mucosa.

Figure 37-10. Type IV rectal prolapse in a postpartum mare.
Clinical Signs and Diagnosis
The usual presentation of a prolapse is a mucosal mass (types I, II, and III) or tube (type IV) protruding beyond the anus, with a variable amount of inflammation, cyanosis, bruising, or necrosis. Colic and peritonitis develop with types III and IV, and abdominocentesis should be performed in such cases.41

Treatment
Most early type I and II prolapses respond to reduction and treatment of the primary problem. In many type I and II prolapses, mucosal edema and irritation can be reduced by topical application of glycerin, sugar, magnesium sulfate, and lidocaine jelly, or lidocaine enemas (12 mL of 2% lidocaine in 50 mL of water).16,17 Epidural anesthesia may be applied to reduce straining and to facilitate manual correction. To prevent recurrence, doubled 6-mm (1/4-inch) umbilical tape can be placed with four wide bites in loose pursestring fashion, 1 to 2 cm lateral to the anus. Normal feces cannot pass through the pursestring, so it has to be opened every 2 to 4 hours to allow defecation or manual removal of feces. Mineral oil enemas and intragastric infusions of mineral oil or other laxatives should be given as needed, and the horse should not be fed for 12 to 24 hours. From then on, a laxative diet should be fed for at least 10 days. If it is well tolerated, the pursestring suture can be left in place for 48 hours. If a horse with a type IV prolapse is to be referred to a hospital for definitive treatment and if the prolapsed tissue appears nonviable, it might be better to leave it prolapsed so the surgeons can evaluate and treat it. Reduction of necrotic tissue can lead to peritonitis and complicate treatment, because access through a celiotomy is limited, especially compared with access to the prolapsed tissue.

If type III and IV prolapses are treated by manual reduction alone, serial peritoneal fluid samples should be obtained to monitor changes in bowel wall viability.38 Frank blood in the rectum after correction of a prolapse may be evidence of bowel necrosis.42 Laparoscopy can be used to determine whether the mesocolon is ruptured and to assess viability of the involved small colon.31 Access for resection of the necrotic bowel may be difficult through a celiotomy, and re-creation of the prolapse might be required to allow a submucosal resection outside the anus. A colostomy could be performed,16,38 but continued necrosis ultimately leads to failure.30

Submucosal Resection
A submucosal resection may be indicated if the prolapsed tissues are devitalized, the prolapse recurs after conservative treatment, or the horse continues to strain.38 The procedure can be performed with epidural or general anesthesia. After preparation for surgery, two 18-gauge, 15.0-cm (6-inch) spinal needles, or 14-gauge, 13-cm (5¼ inch)-long Teflon catheters with the stylet in place are inserted at right angles to each other through the external anal sphincter and healthy mucosa to maintain the prolapse during dissection.38 Starting at the 12 o’clock position, circumferential incisions are made in healthy tissue for one third of the prolapse circumference.38 These incisions should be combined with deep dissection to elevate a strip of edematous and necrotic mucosa and submucosa. Remaining healthy proximal and distal edges of the mucosa and submucosa are apposed with size 1 or 2 medium chronic gut or PDS in an interrupted, horizontal mattress pattern.38 These steps are repeated for each of the remaining thirds of the circumference until all necrotic tissue has been removed.38 Mucosal edges are subsequently apposed with simple-interrupted sutures with buried knots, or preferably with a simple-continuous pattern interrupted at three equidistant points around the circumference.38 A 2-0 absorbable suture material is used for this layer. The purpose of the mucosal suture is to cover all denuded areas and to prevent extensive granulation, scarring, and stricture formation.36 Postoperative management includes laxatives, a laxative diet, and, if necessary, careful digital removal of impacted feces from the rectum.

Resection and Anastomosis
Resection and anastomosis may be indicated for type IV prolapse if the prolapsed tissues are devitalized or too much tissue is involved to allow reduction. The procedure can be performed as for submucosal resection, except that full-thickness circumferential incisions are made through the inner and outer walls of the intussusception in healthy tissue (Fig. 37-11). The healthy proximal and distal edges are apposed with size 1 or 2 PDS in an interrupted, full-thickness, horizontal mattress pattern (Fig. 37-12). These steps are repeated for each of the remaining thirds of the circumference until all necrotic tissue has been removed. Care must be taken during resection to identify and ligate any mesenteric vessels in the prolapse. Mucosal edges are then apposed in a simple-continuous pattern with 2-0 PDS, interrupted at three equidistant points around the circumference. The transfixing cross-needles and the weight of the necrotic tissue through most of the procedure maintain the line of anastomosis outside the rectum. Postoperative management is the same as for submucosal resection.38

Figure 37-11. Treatment of a type IV rectal prolapse with intussusception of the distal part of the small colon and peritoneal segment of the rectum. A, The prolapsed tissues are resected as described and the healthy tissues anastomosed. B, When the stabilizing cross-catheters or needles are released, the anastomosis assumes its position in the proximal part of the rectum. (From Edwards GB: Diseases and surgery of the small colon, Vet Clin North Am Equine Pract 1997;13:359, with permission.)
Prognosis

The prognosis is favorable with types I and II prolapses, but the severity of vascular damage and mesenteric disruption worsens the prognosis for types III and IV prolapses.39,42,44

PERIRECTAL ABSCESS

In most cases, the cause of perirectal abscessation is unknown, although possible causes are rectal puncture or tear, rectal inflammation, and gravitation of a gluteal abscess after injection.45 Enlarged anorectal lymph nodes have been reported as causes of rectal obstruction in young horses (3 to 15 months of age), and such nodes can progress to form abscesses.46 *Streptococcus zooepidemicus* and *Escherichia coli* have been isolated.45,46

Clinical Signs and Diagnosis

The most common signs are low-grade abdominal pain and depression, anorexia, reduced fecal production, dyschezia, tenesmus, and fever.45,46 Urinary tract dysfunction, manifested as dysuria, may develop from neuritis secondary to regional inflammation.46 The abscess can be palpated as a firm submucosal mass. Purulent material can be aspirated through a needle inserted percutaneously or through the rectal mucosa. Ultrasonographic examination is helpful, especially to monitor the response to treatment, but it cannot always provide a clear distinction between a reactive lymph node and an abscess, a hematoma, or a tumor.46

Treatment

Epidural anesthesia or sedation and local anesthesia are used for restraint. A lateral abscess can be drained lateral to the anus, a dorsal abscess can be drained into the rectum, and a ventral abscess can be drained into the vagina in mares or ventral to the anus in males. Postoperatively, the abscess cavity is flushed daily for approximately 6 days with a 10% povidone-iodine solution.45 A laxative diet is fed, and mineral oil is given as needed by nasogastric tube.

Rarely, the abscess may involve abdominal organs and cause peritonitis.45 An exploratory celiotomy may be required to drain the intra-abdominal component by marsupialization or to facilitate drainage into the rectum or vagina. In horses without abdominal involvement, the prognosis for recovery is favorable.45 Surgical drainage does not appear to be necessary in young horses with enlarged or abscessed anorectal lymph nodes, and a successful outcome is possible with treatment by antibiotics, analgesics, laxatives, and diet modification.46

ATRESIAS OF THE ANUS AND RECTUM

Atresia ani is rare47 and may be associated with atresia coli, atresia recti, persistent cloaca, absence of a kidney, renal hypoplasia and dysplasia, absence of the tail, musculoskeletal deformities, microphthalmia, rectourethral fistula, and other urogenital abnormalities.48-56 Atresia coli is also rare (0.44% to 1.3% of hospitalized foals), and affected foals have a normal anus but may have a blind and empty rectum.57

Clinical Signs and Diagnosis

Signs of atresia ani are evident shortly after birth and include straining to defecate, tail flagging, abdominal discomfort, and abdominal distention. The anus is absent, but an anal sphincter may be present (Fig. 37-13). Signs of intestinal obstruction are not seen in foals with atresia and congenital rectovaginal fistula because they can void feces through the vagina. Three of seven foals in one study on atresia coli had atresia of the rectum or a blind-ending...
rectum that could be diagnosed by digital palpation. As with all foals with atresia coli, these foals had a history of failure to pass meconium and a lack of meconium staining of the perineum.

**Treatment**

In foals with a complete rectal pouch, the persistent anal membrane is incised or a small circular piece of skin is removed, and the anal sphincter is spared, if possible. The rectal wall is subsequently sutured to the skin with simple-interrupted sutures. If the distal rectum is atretic, deeper dissection is needed. Any communication with the urogenital tract should be closed by transection between structures and closure by inverting sutures or by simultaneous closure and transection with autosuture instruments (GIA, United States Surgical Corporation). The prognosis for life is favorable, but normal anal function may not be obtained. The prognosis for atresia coli, with or without rectal involvement, is poor.

**POLYPS AND NEOPLASIA**

The most common neoplasms of the perineal region and anus of the horse are squamous cell carcinomas and melanomas. Squamous cell carcinomas are necrotic, foul smelling, and locally invasive lesions that metastasize slowly. Diagnosis is based on biopsy. Treatments include surgical excision, cryosurgery, electrosurgery, laser surgery, hyperthermia, radiation therapy, immunotherapy, and combinations of these methods. Colostomy can be used to bypass rectal obstruction by a large tumor.

Approximately 80% of Gray Horses over 15 years of age have melanomas. Melanomas may be solitary or multiple, and they most commonly occur in the perineum and along the ventral surface of the tail (Fig. 37-14). Although most equine melanocytic tumors are benign, dermal melanomatosis can occur on the perineum and have a high metastatic rate (for details, see Chapter 29). Diagnosis is made by clinical features and biopsy. Treatment is indicated if the lesion is large enough to cause clinical problems or is esthetically unacceptable. The treatment of choice is early excision or cryosurgery, although removal of all lesions in a diffuse cluster is not always feasible or necessary. Successful treatment with radiation therapy, cimetidine, and bacillus Calmette-Guérin has been reported.

Rectal polyps, adenocarcinoma, and leiomyosarcoma are rare in horses and can be treated successfully by transection of attachments to the rectal mucosa. A hamartomatous polyp (focal disordered growth of mature tissue indigenous to the organ affected) obstructed the distal part of the small colon in a 2-day-old Standardbred foal and caused abdominal pain, tenesmus, and rectal bleeding. The mass could be identified on radiographs after a contrast enema, but it was not readily accessible for removal. Rectal strangulation by a mesenteric lipoma has been treated successfully by twisting the lipoma off its pedicle through a colpotomy.

---

**Figure 37-14.** A, A large melanoma that deformed the anus and interfered with defecation. B, The same horse after excision. Penrose drains are placed in the dead space created by the deep perirectal dissection required to remove the large masses completely. Small tumors were not removed so that sufficient skin remained for closure.
REFERENCES

A hernia is a protrusion of an organ or tissue through an abnormal opening.\(^1\) Hernias usually involve protrusion of abdominal contents through part of the abdominal wall, the diaphragm, or the inguinal canal. The defect or opening in the abdominal wall is an important factor in herniation, whether a protrusion through the opening is present or not.\(^2\)

**CLASSIFICATION**

Various classification schemes are used to characterize hernias. One scheme names the hernia by the type of herniated tissue, such as intestine or omentum. Another classification scheme uses epidemiology of the hernia, wherein they are referred to as either congenital or acquired hernias. A congenital hernia is a defect that is present at birth, although the protrusion may not develop until later. In an acquired hernia, the defect occurs after birth and may be to the result of blunt trauma, surgical trauma (wound disruption), degeneration (prepubic tendon rupture in late pregnancy mares), or because of an increased diameter of a normal body opening (inguinal canal).

A third classification scheme defines a hernia by the opening or defect. In true hernias, the protrusion occurs through a normal aperture in the abdomen and contains a complete peritoneal sac (inguinal or scrotal hernia). These hernias are sometimes referred to as indirect hernias. Conversely, in false hernias, the protrusion does not arise through a normal aperture in the abdomen. False hernias do not initially contain a complete peritoneal sac and are usually created by trauma to the abdomen or develop after breakdown of a surgical entry (incisional hernias). These are also referred to as direct hernias.

Hernias may be further categorized as reducible, incarcerated, or strangulated. A hernia is classified as reducible when the protruding hernial contents are freely movable and can readily be manipulated back into the abdominal cavity. When the hernial contents cannot be reduced, the hernia is classified as incarcerated (or irreducible), and this is frequently the result of adhesions that form between the contents and the surrounding tissue, effectively fixing the contents in an abnormal location. Incarceration frequently leads to strangulation when the contents become strangulated. A hernia is classified as strangulated when incarceration obstructs the vascular supply to the herniated tissue, usually at the edge of the defect. Strangulation usually results in tissue necrosis and is the most serious type of hernia.

The anatomic site of herniation is frequently used for classification and allows the best discussion of etiology, clinical signs, and treatment. In this chapter, abdominal hernias are divided into umbilical, ventral midline (incisional), lateral abdominal, diaphragmatic (internal abdominal), and caudal abdominal (inguinal) hernias.

**ANATOMY OF A HERNIA**

Hernias consist of three portions: the ring, the sac, and the contents.\(^2\) The ring forms the actual defect in the limiting wall and may be small or quite large. Wound healing leads to thickening of the leading edge of the ring through collagen maturation, which usually allows its borders to be identified through digital palpation. If this healing results in contraction of the scar, contents may become strangulated. Inflammation in the sac from trauma to the contents frequently leads to incarceration. Loops of intestine frequently move in and out of the ring of the hernia through peristalsis. Sometimes this leads to strangulation when the contents enter at a rate faster than they leave. Additionally, secretion of fluid into the bowel segment located in the hernial sac may cause distention and may eventually lead to strangulation.

The hernial sac is made up of tissues that cover the contents. This usually includes the mesothelial covering. In the initial stages, peritoneum may not line the sac of the hernia; however, chronic hernias are frequently completely lined with peritoneum. Although the contents of an abdominal hernia are usually parts of the intestine, other structures such as the omentum frequently are involved. The type of bowel in the hernial sac frequently predicts the clinical signs that are seen.
ABDOMINAL HERNIAS

CHAPTER 38
Abdominal Hernias
John A. Stick

A hernia is a protrusion of an organ or tissue through an abnormal opening. Hernias usually involve protrusion of abdominal contents through part of the abdominal wall, the diaphragm, or the inguinal canal. The defect or opening in the abdominal wall is an important factor in herniation, whether a protrusion through the opening is present or not.

CLASSIFICATION
Various classification schemes are used to characterize hernias. One scheme names the hernia by the type of herniated tissue, such as intestine or omentum. Another classification scheme uses epidemiology of the hernia, wherein they are referred to as either congenital or acquired hernias. A congenital hernia is a defect that is present at birth, although the protrusion may not develop until later. In an acquired hernia, the defect occurs after birth and may be to the result of blunt trauma, surgical trauma (wound disruption), degeneration (prepubic tendon rupture in late pregnancy mares), or because of an increased diameter of a normal body opening (inguinal canal).

A third classification scheme defines a hernia by the opening or defect. In true hernias, the protrusion occurs through a normal aperture in the abdomen and contains a complete peritoneal sac (inguinal or scrotal hernia). These hernias are sometimes referred to as indirect hernias. Conversely, in false hernias, the protrusion does not arise through a normal aperture in the abdomen. False hernias do not initially contain a complete peritoneal sac and are usually created by trauma to the abdomen or develop after breakdown of a surgical entry (incisional hernias). These are also referred to as direct hernias.

Hernias may be further categorized as reducible, incarcerated, or strangulated. A hernia is classified as reducible when the protruding hernial contents are freely movable and can readily be manipulated back into the abdominal cavity. When the hernial contents cannot be reduced, the hernia is classified as incarcerated (or irreducible), and this is frequently the result of adhesions that form between the contents and the surrounding tissue, effectively fixing the contents in an abnormal location. Incarceration frequently leads to obstruction of the lumen of a hollow viscus, and either signs of bladder or bowel obstruction may be the presenting complaint. A hernia is classified as strangulated when incarceration obstructs the vascular supply to the herniated tissue, usually at the edge of the defect. Strangulation usually results in tissue necrosis and is the most serious type of hernia.

The anatomic site of herniation is frequently used for classification and allows the best discussion of etiology, clinical signs, and treatment. In this chapter, abdominal hernias are divided into umbilical, ventral midline (incisional), lateral abdominal, diaphragmatic (internal abdominal), and caudal abdominal (inguinal) hernias.

ANATOMY OF A HERNIA
Hernias consist of three portions: the ring, the sac, and the contents. The ring forms the actual defect in the limiting wall and may be small or quite large. Wound healing leads to thickening of the leading edge of the ring through collagen maturation, which usually allows its borders to be identified through digital palpation. If this healing results in contraction of the scar, contents may become strangulated. Inflammation in the sac from trauma to the contents frequently leads to incarceration. Loops of intestine frequently move in and out of the ring of the hernia through peristalsis. Sometimes this leads to strangulation when the contents enter at a rate faster than they leave. Additionally, secretion of fluid into the bowel segment located in the hernial sac may cause distention and may eventually lead to strangulation.

The hernial sac is made up of tissues that cover the contents. This usually includes the mesothelial covering. In the initial stages, peritoneum may not line the sac of the hernia; however, chronic hernias are frequently completely lined with peritoneum. Although the contents of an abdominal hernia are usually parts of the intestine, other structures such as the omentum frequently are involved. The type of bowel in the hernial sac frequently predicts the clinical signs that are seen.
SIGNS OF HERNIATION

Most external abdominal hernias have swelling as a classic sign. However, internal abdominal hernias (diaphragmatic hernias) frequently show signs attributed to intestinal obstruction or respiratory problems. In uncomplicated external hernias, no pain may be elicited on palpation, and the consistency of the swelling depends on the contents. When inflammation or infection or luminal distention of a viscus is present, a definitive diagnosis is difficult to make on palpation alone. Also, the site of the swelling may be some distance from the actual hernial ring, as contents can migrate into the subcutaneous space. However, a tentative diagnosis is frequently made on the basis of clinical signs and location of the swelling. Palpation becomes an important part of the examination to determine if the hernia is reducible, incarcerated, or strangulated. Infrequently, radiography shows luminal gas distention if the hernia contents are bowel in origin. Diagnosis is frequently confirmed by reduction of the hernia and palpation of the hernial ring. The incarcerated hernia presents more of a diagnostic challenge, and ultrasonography is the diagnostic modality of choice in these instances. Fine-needle aspiration to try to rule out hernial contents is contraindicated, as it frequently results in contamination of an otherwise uninfected site.

UMBILICAL HERNIAS

The most common type of hernia in the horse is umbilical in origin and is estimated to occur in 0.5% to 2.0% of foals (Fig. 38-1). Most umbilical hernias are congenital and may have a hereditary component. In a recent study of the closure of a body wall defect at the umbilicus, 19 of 44 foals had a defect in the body wall at the umbilicus with a palpable umbilical ring at birth. This defect closed within 4 days in 18 of these foals. Additionally, in this same study, 12 of 44 foals developed an umbilical hernia between 5 and 8 weeks of age.

Figure 38-1. Typical appearance of an umbilical hernia in a 3-day-old foal. The majority of umbilical hernias in foals at this age spontaneously regress within the first 3 weeks of life.

Etiology

The development of umbilical hernias has been attributed to trauma to the umbilical cord during birth, excessive straining, and umbilical cord infection. Very rarely, evisceration occurs immediately after the birth as a result of trauma to the umbilical cord. This condition necessitates emergency surgical reconstruction in the abdominal wall. However, in most foals, umbilical hernias are chronic in nature, small, and uncomplicated by underlying organic diseases. They usually represent a cosmetic defect but are a potential site of bowel incarceration. In fact, between 8% and 10% of umbilical hernias referred to tertiary hospitals sustain complications that are life threatening and mandate emergency surgery.

Diagnosis

Digital palpation of the hernia determines the size and shape of the hernial ring, the nature of the contents of the sac, and the reducibility of the hernia. Firm, thickened rings hold sutures quite well during herniorrhaphy, whereas a thin and indistinct ring is an indication that repair may be more difficult. Hernial sacs usually contain subperitoneal fat, omentum, or intestine. These hernias are almost always reducible and are rarely incarcerated. However, when incarceration does occur, strangulation of a portion of the intestinal wall is usually suspected. In some instances, only a portion of the intestinal wall is incarcerated (Richter’s hernia or parietal hernia), and luminal wall destruction usually does not occur. When incarceration is present, any increase in hernia size, firmness, edema, or pain on palpation is an indication that surgery should be undertaken as soon as possible. Umbilical hernias need to be differentiated from abscessation and local infection of the umbilical cord and associated structures. Ultrasonographic examination of the hernia and ventral abdominal wall is indicated to determine the nature of the hernial contents in complicated hernias of this type (Fig. 38-2).

Treatment

Reducible umbilical hernias less than 5 cm in diameter frequently close spontaneously as the foals mature. Daily digital reduction of the hernia is indicated to monitor for changes in size or incarceration of hernia contents. Hernias that are not spontaneously regressing by the time the foal is 4 months old should be surgically repaired.

Umbilical hernias greater than 10 cm in diameter are not treated with conservative methods because the risk of strangulating obstruction is so great. Additionally, a hernia of that size very rarely closes on its own. Although most umbilical hernia repairs are elective procedures and are performed on foals for cosmetic reasons, obviously strangulating obstructions of the small intestine necessitate emergency repair.

Two methods have been historically used for repairing hernias. The application of a hernia clamp is one method of management, but this is not commonly practiced and therefore is not part of this discussion. It poses a serious complication if entrapment of the intestine into the hernial clamp occurs, and this has led to intestinal obstruction,
peritonitis, or enterocutaneous fistulas. Also, inadvertent dislodging of the clamp has led to eventration. Because of these complications, this technique is strongly discouraged.

Surgical repair of umbilical hernias is accomplished with the horse in dorsal recumbency and under general anesthesia. Careful preparation of the surgical site is especially important in male foals, in which the preputial orifice should be temporarily closed with sutures to reduce contamination during surgery. Surgical repair is initiated by making an elliptical skin incision around the hernia, with the points of the ellipse cranial and caudal (Fig. 38-3). Skin and loose subcutaneous tissue are removed to expose the external sheath of the rectus abdominal muscle. Sharp dissection generally results in less swelling than blunt dissection in this area, and this dissection is continued to about 1 cm peripheral to the hernial ring. The hernial sac can be inverted and the hernia repaired without removal (closed technique). However, the sac is usually removed (open technique). To do this, the hernial sac is incised along the edge of the hernial ring (see Fig. 38-3, E). The contents of the sac are examined. It is unusual, but abscesses in the umbilical veins and umbilical remnants can be entered at this point, and care should be taken, especially in the caudal aspect of the incision, to prevent such mishaps. Once the contents have been inspected and appropriately treated, the body wall should be closed. Varying suture materials and patterns can be used; however, a nicer closure without a dog-ear can be achieved if the ventral body wall defect is converted to an ellipse with the point cranial and caudal, similar to the skin incision before closure. A simple-continuous appositional suture pattern is recommended using appropriate-size absorbable suture material. Synthetic monofilament absorbable suture material (1, 2, or 3) is selected on the basis of the body size of the patient. Thereafter, the subcutaneous tissues and skin are closed independently, once again using absorbable suture material in a simple-continuous pattern.

**Aftercare**

An abdominal support wrap is applied to decrease dead space and reduce edema for about 48 hours. The foal should be confined for 30 to 45 days. Skin sutures do not need to be removed if absorbable suture material has been used. Although laparoscopic surgery is described (see Chapter 71) for disorders of the foal umbilical structures, there are few indications for laparoscopic surgery of umbilical hernias.

**VENTRAL MIDLINE HERNIAS**

Ventral hernias usually occur as a result of inadequate healing of a previous incision or excessive strain at the site of an abdominal wall scar (Fig. 38-4). Obesity, age, and wound infection are the most common predisposing causes in people,² and the incidence is between 1% and 11%. Risk factors for incisional hernias in dogs include intra-abdominal pressure because of pain, entraped fat between hernia edges, inappropriate suture material use, chronic steroid treatment, and infection.³ Although sequelae to incisional hernias are often serious and costly, the incidence is much lower in small animals.

In horses, large abdominal wall defects commonly arise from partial incisional dehiscence after ventral midline celiotomy or after failed umbilical herniorrhaphy. Incisional herniation is strongly associated with wound separation. With the proper suture placement, suture selection (in terms of size and material), and soft tissue handling using aseptic technique, primary-intention healing of a ventral midline incision usually occurs. Experimentally, optimal bite size is 15 mm from the incision edge (1/2 inch).⁴ Ninety-three percent of sutures fail at the knot and suture loops fail
before complete fascial disruption. The strongest synthetic absorbable suture materials tested were 3 polyglactin 910 and 2 polyglycolic acid. Because the linea alba is thickest near the umbilicus and tends to become thinner cranially, it has been suggested that the cranial portion of the linea alba may be more susceptible to dehiscence. Clinically, the hernias that develop are usually located in the cranial portion of the incision rather than near the umbilicus. In one study of 210 horses undergoing midline celiotomy for abdominal disease, the incisional hernias were as high as 16%, and all hernias were evident within 4 months of surgery.9

Figure 38-3. Illustrations of umbilical hernia repair. A, An elliptical skin incision is made around the hernial sac. The skin is dissected free from the hernial sac and discarded. B, The hernial ring is dissected free from the surrounding hernial sac so that the ring can be clearly identified. C, The sac can be inverted and the ring prepared for suturing, or the hernial sac can be removed. (The latter technique allows the round hernial ring to be converted into an ellipse for easier closure.) D, The ring is closed with a simple-continuous suture of appropriate-size suture material, and the subcutis and skin are closed in separate layers. E, In most cases, the open technique is applied: the hernia sac is excised and, after brief inspection of the abdominal cavity, the abdominal wall is closed in three layers.
In addition to sepsis, other factors that may affect breakdown of an incision are abdominal distention immediately after recovery, and incisional trauma from excessive struggling during recovery from general anesthesia, or from rolling associated with uncontrolled postoperative pain.\(^4\) For the purposes of treatment, incisional hernias may be broken down into two types: acute total dehiscence and chronic insidious hernia formation.

**Acute Total Dehiscence**

Disruption of the abdominal incision that occurs within the first 4 to 7 days after surgery constitutes an emergency to prevent evagination. A belly bandage should be applied for support and the horse anesthetized for the repair. Complete acute dehiscence is detected by observing excessive peritoneal fluid leaking from the incision and palpable gaps in the sutured abdominal wall. The horse is placed in dorsal recumbency and all sutures are removed and the site prepared for surgery.

All devitalized tissue is sharply incised and removed. The wound is cultured and thoroughly flushed. The septic surgical closure uses monofilament stainless steel wire to close the abdominal wound. This is a through-and-through interrupted vertical mattress pattern, with sutures placed 2 to 3 cm apart. The wire is passed through hard rubber tubing used as stents before the close bites of the vertical mattress pattern are placed. These bites are taken 2.5 cm from the wound edge (Fig. 38-5). The wire is passed through hard rubber tubing used as stents before the close bites of the vertical mattress pattern are placed. These bites are taken 2.5 cm from the wound edge (Fig. 38-5). The wire is passed through hard rubber tubing used as stents before the close bites of the vertical mattress pattern are placed. These bites are taken 2.5 cm from the wound edge. This is a through-and-through interrupted vertical mattress pattern, with sutures placed 2 to 3 cm apart. This suture is passed through skin, fascia, and rectus abdominal muscle about 5 cm from the wound edge (Fig. 38-5). The wire is passed through hard rubber tubing used as stents before the close bites of the vertical mattress pattern are placed. These bites are taken 2.5 cm from the wound edge.

Prior to recovery, a self-adhering drape is placed over the incision, and after recovery, a sterile abdominal compress is secured with Elasticon to form an abdominal bandage. The bandage compress should be changed every 24 hours until the incisions have healed (at about 30 days). Beginning the 14th day after surgery, alternate wire sutures and rubber tubing are removed, and all remaining sutures are removed on day 21. Daily cleaning of the wound is necessary, as well as re-bandaging until the skin is healed.

**Chronic Incisional Hernias**

The factors responsible for acute total wound disruption usually are the same as the cause of partial dehiscence and eventual hernia formation. Incisional infection is usually part of the medical history preceding hernia formation.\(^10\)

Many hernias can be managed conservatively. If infection is present, the wound should be cultured for bacterial growth and the animal treated with appropriate antimicrobial agents. Sterile abdominal compresses may require daily changing. Flushing is not recommended because of the likelihood of disseminating the infection subcutaneously to other sutured portions of the incision. Chronic abdominal bandaging for 1 to 2 months during treatment of the wound infection reduces the size of the hernia. In some cases, chronic wound bandaging for up to 6 or 8 months will eliminate the necessity for surgical repair of a wall defect. To decrease the amount of disposable bandaging material necessary to accomplish this, commercially available reusable elastic bandages (Surgimed, Hospital Marketing Services, Inc, Naugatuck, Conn) can be purchased and have been used successfully in a number of cases.

When the hernia has failed to heal or enlarges after turnout, surgical repair becomes necessary, especially if the horses are used in an athletic capacity. Large defects in the abdominal wall require prosthetic reconstruction with a synthetic mesh and are preferentially repaired in this manner. Knit polypropylene mesh (Marlex) is strong, elastic, and inert, and it resists infection. Tissue grows through the knit mesh to be incorporated into the healing herniorrhaphy tissue. Failure to use the synthetic mesh in the repair usually results in enough tension to produce a recurrence of the hernia. All infection should be eradicated before prosthetic reconstruction of the defect. This may require surgical removal of infected suture material from sinus tracts (see Chapter 28).
Prophylactic antimicrobial therapy is indicated because most incisional hernias have had some type of infection, and small pockets of bacteria may remain when surgical herniorrhaphy is undertaken. The horse is placed in dorsal recumbency under general inhalation anesthesia and a strict aseptic technique is used. The skin is incised for 180 degrees at the margin of the hernial ring (Fig. 38-6, A). Likewise, the fascia and fibrous tissue overlying the hernial ring are incised along the same planes. This fascia is removed using retroperitoneal dissection, leaving the peritoneum intact. The mesh is placed retroperitoneally and subfascially. In some cases, this is not possible, because there is an adhesion between the peritoneum and the fascia, or there is such a thin fascia that it cannot be separated. Then only intraperitoneal and subfascial placement is possible. A single layer of mesh is cut to correspond to the size and contour of the defect, allowing the edges of the mesh to be folded over so the sutures pass through a double layer.

Horizontal mattress sutures are placed about 2.5 cm from the cut edge of the mesh. Each bite is approximately 2.5 cm wide. Sutures are placed 0.5 cm apart (close enough together to prevent the small intestine from becoming incarcerated between the sutures). Number 2 polypropylene suture material is used. The sutures are pre-placed so that when they are tied, the mesh should lie flat and snugly under a moderate amount of tension deep to the hernia ring. The hernial flap then is trimmed and the free edge sutured to the hernial ring for reinforcement of the hernial mesh (see Fig. 38-6, D). Simple-continuous synthetic absorbable sutures may be used. Subcutaneous tissues and skin are closed in a routine fashion. All redundant subcutaneous tissues and skin are trimmed so that the skin also is under a moderate amount of tension when closed.

On recovery from surgery, an abdominal bandage is used for 7 to 10 days to prevent edema and seroma formation. Parenteral antibiotics are discontinued on the second or third day after surgery. Horses are confined to a stall for 60 days with hand-walking only.

LATERAL ABDOMINAL HERNIAS

Lateral abdominal hernias are usually the result of blunt trauma injuries from farm machinery, fence posts, or kicks from other horses (Fig. 38-7). Penetrating abdominal wounds may require immediate reconstruction to prevent evisceration, peritonitis, and wound infection. However, more commonly, traumatic wounds are not penetrating, and the horse can be treated with local therapy and abdominal bandaging. After 60 days, small residual defects in the body wall can be treated by direct suture apposition. When they are very large, they can be treated by prosthetic reconstruction with synthetic mesh, as previously described.

Abdominal wall hernias in pregnant mares that do not involve rupture of the prepubic tendon can be similarly repaired. However, it is suggested that the pregnancy be terminated by cesarean section if repair is necessary before parturition.

DIAPHRAGMATIC HERNIAS

Internal abdominal hernias include a multitude of intestinal accidents, including mesenteric hernias, entrapment in the epiploic foramen, and diaphragmatic hernias. Although diaphragmatic hernias are rare, both congenital and acquired hernias have been described.1 1-13 Diaphragmatic hernias can be congenital, resulting from failed fusion of many of the four embryonic components of the diaphragm, or acquired from trauma. Diaphragmatic hernias can be classified by anatomic location as peritoneal pericardial or peritoneal pleural, depending on where the tear occurs and into which thoracic compartment bowel enters. Congenital defects usually have smooth round edges, and some hernias can be quite small, only 2.5 cm in diameter. On the other hand, acquired diaphragmatic hernias, because they are associated with some form of violence and increased intra-abdominal pressure, are usually large and frequently originate along the dorsal body wall.

Diaphragmatic hernias result in low-grade, chronic recurrent abdominal pain and sometimes are found incidentally at necropsy. However, this is the exception; more commonly, horses are presented in distress with either a serious abdominal crisis (subsequently found during exploratory celiotomy) or in acute respiratory distress. Diagnosis can be made on physical examination, with borborygmi auscultated during examination of the thorax. However, other signs associated with the acute abdominal crisis may be equivocal, since a rectal examination and abdominocentesis may not be abnormal. Ultrasonography is quite accurate in revealing gas-filled loops of intestine in the thorax (Fig. 38-8). Likewise, radiography may show a loss of the diaphragmatic line at the level of the hernia, or more commonly, radiopacity in the ventral aspect of the chest. Occasionally, gas-filled loops of large colon can be visualized on thoracic radiographs (Fig. 38-9).

Repair of the diaphragmatic hernia is accomplished with the horse placed in dorsal recumbency and with a ventral midline celiotomy that extends cranially to the xiphoid. Assisted ventilation is necessary during anesthesia. Abdominal viscera should be repositioned into the abdomen, and tilting the horse with front end elevated may aid in reduction of the hernia.

Small defects (less than 5 cm), particularly those ventrally positioned, may be closed by primary apposition using large-gauge suture material in a simple-continuous pattern. Débridement is usually not undertaken, because once the hernial ring is removed, the muscular portion of the diaphragm is less likely to hold sutures as well as the hernial ring. Larger defects require prosthetic reconstruction with a synthetic mesh. The mesh is secured to the perimeter of the defect with simple-interrupted horizontal mattress sutures similar to those used for mesh herniorrhaphy for the ventral midline. Sutures are pre-placed prior to tying to ensure that tension is maintained on the mesh. The mesh is preferentially placed on the abdominal side of the incision.

Traumatic diaphragmatic hernias are quite often associated with very large defects, dorsally positioned, and inaccessible, precluding safe closure. In these instances, thoracotomy is used to gain better access. The diaphragm holds sutures quite well if a linear tear has occurred, and mesh reinforcement may not be necessary. Prior to closing the abdominal incision, the lungs should be maximally inflated to expel as much air as possible from the thorax. A chest tube with a Heimlich valve (see Chapter 18) should be used to manage a pneumothorax.
Figure 38-6. Illustrations of herniorrhaphy using a synthetic mesh and fascial overlay. A, Semi-elliptical incision extending beyond the cranial and caudal margins of the hernia is made. B, The skin flap and subcutaneous tissue are reflected off the hernia and held with towel clamps. The fibrous hernial sac is then reflected toward its attached base, leaving the peritoneum in place if possible. C, The mesh is anchored on the inside of the abdominal wall with through-and-through horizontal mattress sutures. Some of these are pre-placed. D, The fascial overlay is then sutured back in place using simple interrupted or a simple-continuous suture. E, Routine closure of the skin follows.
Dehiscence of the repair is not uncommon, and rupture of the diaphragm in another location has been reported. Prognosis for diaphragmatic hernia repair is guarded.

### CAUDAL ABDOMINAL (INGUINAL) HERNIAS

Bilateral congenital inguinal hernias are often encountered in young colts, but they usually resolve without surgery during the first few weeks of life. The colt is confined to a box stall and observed, and the owner is instructed how to manually reduce the hernia several times daily. Larger hernias may benefit from support provided by an inguinal bandage constructed from rolled cotton and gauze. Reduction of the hernia is usually facilitated by casting the animal in lateral recumbency. For surgical descriptions of repair of inguinal hernias including via laparoscopy, please refer to Chapter 65.

By definition, inguinal hernias are present when there are intestinal contents in the inguinal canal. Scrotal hernias occur when the contents continue on into the scrotum. However, the term inguinal hernia is usually used to refer to both disorders. Distal jejunum and ileum are the intestinal contents most commonly encountered in inguinal hernias, but omentum and even the small colon are sometimes involved. Equine inguinal hernias usually are indirect (or true) hernias, with the contents passing through the vaginal ring and into the vaginal tunic. In a direct (or false) inguinal hernia, which occurs in humans, the contents do not pass through the ring but protrude through a weakness in the body wall. This occasionally can occur in foals, but it is highly unusual.

The clinical sign of an inguinal hernia is scrotal swelling. The testicle is often cool in the adult horse, probably because of vascular compromise. Frequently, the spermatic cord is enlarged and extremely hard and very painful to the touch. All stallions with colic should be checked for this type of inguinal hernia. Frequently, scrotal herniation in foals occurs without intestinal incarceration and may be the result of abdominal straining. Before repair is undertaken, conservative management may be advisable for several weeks. Diagnosis of inguinal hernias is made on the basis of external palpation, and rectal palpation in adult horses permits further evaluation of the internal inguinal ring. Intestinal incarceration in the ring can be easily palpated. Differential diagnoses include thrombosis of the testicle; testicular artery, seroma, or hematoma of the scrotum; neoplasia; and torsion of the spermatic cord.

CHAPTER 39

Postoperative Care and Complications Associated with Abdominal Surgery
Joanne Hardy
Peter C. Rakestraw

Postoperative management of horses with abdominal disorders should be targeted toward identification and management of pain, support of the cardiovascular system, treatment of endotoxemia, identification and treatment of surgical infection, restoration of gastrointestinal function, and management of secondary complications (diarrhea, thrombophlebitis, laminitis). Disorders of the gastrointestinal (GI) tract can result in significant systemic derangements in affected horses. Strangulating lesions lead to intestinal distention proximal to the lesion, third-space pooling of fluid in the intestinal tract, and intestinal mucosal damage with subsequent endotoxin absorption. Despite correction of the primary condition, problems encountered in the postoperative period usually represent a natural progression of the events triggered by the primary lesion. This chapter reviews the management of horses after abdominal surgery and addresses complications related to specific surgical procedures.

FLUID THERAPY

Dehydration and electrolyte imbalances are commonly encountered as a result of abdominal disorders. Even though a horse is stabilized in the perioperative period and the primary problem is corrected, continued replacement of previous and ongoing fluid losses is critical to a successful outcome. Knowledge of basic electrolyte and fluid homeostasis is essential to the successful management of these cases (see Chapter 3). The daily maintenance fluid requirement in adult horses is 50 to 60 mL/kg, and in foals, 70 to 80 mL/kg. The volume of GI secretions in adult horses is equivalent to their extracellular fluid volume, approximately 30% of body weight. With ileus or diarrhea, these fluids are not reabsorbed by the large colon, resulting in considerable fluid losses. These losses must be added to the maintenance requirements. Fluids available for replacement therapy in horses include lactated Ringer’s solution (Baxter Healthcare Corp, Deerfield, Ill), which contains lactate as a buffer and calcium (4 mEq/L), PlasmaLyte A (Baxter Healthcare Corp), and Normosol-R (Abbott Laboratories, North Chicago, III), which do not contain calcium but have acetate or gluconate as buffer sources. Intravenous fluid administration systems are commercially available (Baxter Laboratories, Deerfield, Ill) and provide a convenient method of administering large volumes of fluid to horses.

A significant complication of endotoxemia, particularly in postoperative cases of large colon torsion with significant mucosal damage, is increased capillary permeability resulting in fluid and protein loss into the interstitium. Vascular volume can be difficult to maintain in these horses because of the tremendous fluid loss in both the interstitium and the GI tract and the development of hypoproteinemia. The goal of therapy is to maintain enough vascular volume to sustain cardiac output. A reasonable indicator is the ability to maintain the heart rate at less than 80 beats per minute, packed cell volume (PCV, hematocrit) at less than 30%, and total protein at greater than 4.1 g/dL. PCV and total protein should be measured every 6 hours and therapy adjusted accordingly. If plasma protein decreases to less than 4.1 g/dL (corresponding to a plasma oncotic pressure of 12 mm Hg), it may be necessary to administer colloids to prevent severe edema and allow continued administration of fluids. In surviving patients, capillary permeability is restored within 24 to 36 hours. Plasma proteins that were lost into the interstitium are quickly reabsorbed, and plasma protein concentration returns to normal range within a few days. Available colloids for administration to horses include plasma and synthetic colloids such as dextrans and hydroxyethyl starch.

CHAPTER 39

Postoperative Care and Complications Associated with Abdominal Surgery
Joanne Hardy
Peter C. Rakestraw

Postoperative management of horses with abdominal disorders should be targeted toward identification and management of pain, support of the cardiovascular system, treatment of endotoxemia, identification and treatment of surgical infection, restoration of gastrointestinal function, and management of secondary complications (diarrhea, thrombophlebitis, laminitis). Disorders of the gastrointestinal (GI) tract can result in significant systemic derangements in affected horses. Strangulating lesions lead to intestinal distention proximal to the lesion, third-space pooling of fluid in the intestinal tract, and intestinal mucosal damage with subsequent endotoxin absorption. Despite correction of the primary condition, problems encountered in the postoperative period usually represent a natural progression of the events triggered by the primary lesion. This chapter reviews the management of horses after abdominal surgery and addresses complications related to specific surgical procedures.

FLUID THERAPY

Dehydration and electrolyte imbalances are commonly encountered as a result of abdominal disorders. Even though a horse is stabilized in the perioperative period and the primary problem is corrected, continued replacement of previous and ongoing fluid losses is critical to a successful outcome. Knowledge of basic electrolyte and fluid homeostasis is essential to the successful management of these cases (see Chapter 3). The daily maintenance fluid requirement in adult horses is 50 to 60 ml/kg, and in foals, 70 to 80 ml/kg. The volume of GI secretions in adult horses is equivalent to their extracellular fluid volume, approximately 30% of body weight. With ileus or diarrhea, these fluids are not reabsorbed by the large colon, resulting in considerable fluid losses. These losses must be added to the maintenance requirements. Fluids available for replacement therapy in horses include lactated Ringer’s solution (Baxter Healthcare Corp, Deerfield, Ill), which contains lactate as a buffer and calcium (4 mEq/L), PlasmaLyte A (Baxter Healthcare Corp), and Normosol-R (Abbott Laboratories, North Chicago, Ill), which do not contain calcium but have acetate or gluconate as buffer sources. Intravenous fluid administration systems are commercially available (Baxter Laboratories, Deerfield, Ill) and provide a convenient method of administering large volumes of fluid to horses.

A significant complication of endotoxemia, particularly in postoperative cases of large colon torsion with significant mucosal damage, is increased capillary permeability resulting in fluid and protein loss into the interstitium. Vascular volume can be difficult to maintain in these horses because of the tremendous fluid loss in both the interstitium and the GI tract and the development of hypoproteinemina. The goal of therapy is to maintain enough vascular volume to sustain cardiac output. A reasonable indicator is the ability to maintain the heart rate at less than 80 beats per minute, packed cell volume (PCV; hematocrit) at less than 50%, and total protein at greater than 4.1 g/dL. PCV and total protein should be measured every 6 hours and therapy adjusted accordingly. If plasma protein decreases to less than 4.1 g/dL (corresponding to a plasma oncotic pressure of 12 mm Hg1), it may be necessary to administer colloids to prevent severe edema and allow continued administration of fluids. In surviving patients, capillary permeability is restored within 24 to 36 hours. Plasma proteins that were lost into the interstitium are quickly reabsorbed, and plasma protein concentration returns to normal range within a few days. Available colloids for administration to horses include plasma and synthetic colloids such as dextrans and hydroxyethyl starch.
Colloids
Plasma provides a source of protein, coagulation factors, and antithrombin III (AT-III). Plasma should be thawed slowly in a 37°C water bath if preservation of coagulation factors is desired and then used immediately. Storage of frozen plasma for more than 1 year or of thawed plasma for more than 24 hours at 1°C to 6°C can result in significant deterioration of coagulation factors, particularly factors V and VIII. Plasma should be administered slowly, using an in-line filter, to avoid adverse reactions. The volume of plasma to be given can be estimated as

\[ \text{vol of plasma} = (\frac{\text{PPg} - \text{PPr}}{0.05 \text{BW}r}) \times \text{PPr} \]

where PPg is the goal plasma protein concentration, PPr and PPr are the plasma protein of the recipient and donor, respectively, and BWr is the body weight in kilograms of the recipient. Usually, a volume of 2 to 4 mL/kg is sufficient to raise the plasma protein to greater than 4.1 g/dL, but repeated administration may be required.

Dextran 70 has a 6-hour and dextran 40 a 2-hour half-life. These colloids are available as a 6% solution containing 3 mEq/L of elemental Mg. This amount may be insufficient to account for the increased losses in sick horses. Administration of 150 mg/kg per day of MgSO4 (0.3 mL/kg of a 50% solution), equivalent to 14.5 mg/kg per day or 1.22 mEq/kg per day of elemental magnesium, administered in saline, dextrose, or polyionic fluids would provide daily requirements for the horse.

Hypokalemia may develop because of lack of intake, diuresis, and GI loss through diarrhea. Horses with a metabolic acidosis can become hyperkalemic, and potassium excretion can occur after correction of the acidosis. Measurement of serum potassium as an estimate of total body potassium can be misleading, because most of the potassium ion is intracellular. Routine potassium supplementation is indicated if a lack of both intake and fluid therapy is continued for more than 24 hours. It is recommended that, to avoid any complication, animals not receive more potassium than 0.5 mEq/kg per hour. Most horses benefit from the addition of 12 mEq of potassium chloride per liter of fluids (80 mEq per 5-L bag).

Acid-base imbalances are uncommon in horses with acute abdominal disorders unless they are severely dehydrated and compromised, in which case a metabolic acidosis can be present. Rehydration and establishment of renal function often leads to correction of the acidosis. Correction of a metabolic acidosis is not recommended or necessary unless the pH is less than 7.2, blood bicarbonate is less than 15 mEq/L, or base excess deficit is greater than 10 mEq/L. Half the calculated requirement of bicarbonate can be administered over 1 hour, with the remainder administered over 12 to 24 hours. Concurrent rehydration should always be established. Care should be taken to minimize bicarbonate administration in severely distended animals with respiratory impairment until distention is corrected, to avoid accumulation of carbon dioxide.

ENDOTOXEMIA
Endotoxemia in horses causes decreased circulating vascular volume, increased capillary permeability, ileus, and coagulation disorders. It is manifested clinically as pain, tachycardia, edema, hypomotility, intestinal distention, nasogastric reflux, and thrombosis or bleeding tendencies. Hypo-
volemia results from GI stasis with losses through nasogastric reflux, increased capillary permeability resulting in fluid loss into the intestinum, and maldistribution of fluids with venous pooling. The increased capillary permeability typically observed with endotoxemia also results in protein loss (particularly of albumin) and potential edema formation. Fluid therapy is an important part of the treatment of the hypovolemia associated with endotoxemia and must be carefully adjusted to prevent significant hypoproteinemia. If plasma proteins fall to less than 4.1 g/dL, plasma administration should be considered.

Potential strategies to decrease endotoxin activity include prevention of absorption, chelation and elimination of the endotoxin molecule, and pharmacologic management of the cascade of mediators triggered by endotoxin. Endotoxin absorption can be minimized by restoring and maintaining mesenteric blood flow, which will preserve mucosal integrity, by decreasing luminal contents through emptying of the GI tract, and by luminal binding and inactivation of endotoxin. Luminal lavage, particularly after correction of a large colon volvulus, has been recommended to decrease the luminal endotoxin load. Administration of activated charcoal has also been recommended to bind endotoxin and prevent its absorption. Recently, di-tri-octahedral smectite (Bio-sponge, Platinum Performance, Buellton, Calif) has been shown to actively bind endotoxin and clostridial enterotoxin.\textsuperscript{8,10} Its administration has been recommended for use in horses with colitis as well as in horses at risk for the development of postoperative diarrhea. Intraoperative administration through the pelvic flexure enterotomy after the large colon has been lavaged is easily performed. The use of endotoxin adsorbsent through hemofiltration has been investigated but has not been attempted in horses. Although oral administration of antibiotics such as neomycin to decrease colonic bacterial content is recommended in other species, this is generally not recommended in horses because of the risk of drug-induced colitis.

Currently, two therapeutic agents are recommended to bind circulating endotoxin; hyperimmune plasma/serum or polymyxin B. Hyperimmune serum is prepared by harvesting serum from horses immunized with the lipid A core of Salmonella typhimurium,\textsuperscript{11} Escherichia coli,\textsuperscript{12,13} and a Remutant Salmonella typhimurium product (Endoserm, IMMVAC Inc, Columbia, Mo). These products must be administered diluted. Although they are used in many equine hospitals, documentation of efficacy via randomized clinical trials has not been performed. Recently, four fatal cases of serum hepatitis associated with the administration of commercial plasma to horses have been described.\textsuperscript{15} Although uncommon, the potential for complications when administering plasma should be considered. Active immunization through vaccination is also promoted by one company (ENDOVAC-equine, IMMVAC Inc, Columbia, Mo). Although a rapid anamnestic response would theoretically be advantageous in a horse acutely exposed to endotoxin, the benefit of prior immunization has not been demonstrated.

Polymyxin B is a cyclic cationic polypeptide antibiotic that binds lipid A and neutralizes the actions of endotoxin in vitro and has been used to prevent and treat endotoxemia in human patients.\textsuperscript{13} In an experimental study performed in foals given low-dose endotoxin, pretreatment with polymyxin B resulted in lower rectal temperature, respiratory rate, and plasma tumor necrosis factor (TNF) and interleukin-6 (IL-6) activities compared with saline pretreatment. Interestingly, in that study, hyperimmune serum worsened the endotoxin response. Polymyxin B was given at a dosage of 6000 IU/kg intravenously (IV). In another study,\textsuperscript{14} polymyxin B treatment before or after administration of endotoxin significantly reduced fever, tachycardia, and serum TNF compared with horses receiving saline.

Detergents consisting of a polyethylene oxide polymer of p-tert-octophenol,\textsuperscript{15} or phospholipids,\textsuperscript{16} when administered as a pretreatment to horses given endotoxin, resulted in decreased pulmonary artery hypertension, absence of leukopenia, and absence of fever, suggesting a beneficial effect in attenuating the response to endotoxin. Clinical efficacy or safety of these products has not been determined. Concerns over adverse effects, such as hemolysis, during administration have precluded their use in a clinical setting.\textsuperscript{16}

Pharmacologic targeting of inflammatory mediators triggered by endotoxin is an effective modality in the management of endotoxemia. Endotoxin stimulates the release of several mediators, including eicosanoids and cytokines. Nonsteroidal agents, particularly flunixin meglumine, are used routinely to decrease endotoxin-mediated prostaglandin (PG) release. At low doses, flunixin inhibits the PG-mediated vasodilator effects of endotoxin and may minimize the hypotension observed after an acute endotoxic event. Phenylbutazone was more efficacious than flunixin in improving endotoxin-mediated ileus.\textsuperscript{17} Ketoprofen can also be administered to mediate the endotoxin-mediated PG release. It has the advantage of being less ulcerogenic than flunixin or phenylbutazone.\textsuperscript{18} Claims of ketoprofen’s inhibitory effect on the lipoxygenase pathway have not been substantiated. In vitro treatment of ischemia-injured equine jejunum with flunixin meglumine was shown to retard recovery of barrier function.\textsuperscript{19} Subsequent in vivo studies confirmed that nonselective inhibition of PG production by flunixin meglumine retarded mucosal recovery and prolonged the increased mucosal permeability induced by ischemia.\textsuperscript{20,21} The clinical consequences of these findings are not documented, but the beneficial analgesic, anti-inflammatory, and antienterotoxic effects or these drugs may outweigh the potential deleterious effect on intestinal barrier function.

Endotoxin results in significant macrophage release of TNF and significant increase in pro-coagulant activity. Pentoxifylline, a methylxanthine derivative, is a vasodilator; it improves RBC rheology, decreases platelet aggregation, and may improve microcirculation.\textsuperscript{22} In addition, pentoxifylline decreases TNF and IL-6 release by macrophages and thromboxane B\textsubscript{2} by platelets. Currently, only an oral formulation is available, given at a dosage of 8.5 mg/kg every 12 hours.\textsuperscript{22} The vasodilatation and decreased thrombin formation may also be beneficial in lamineitis prevention.

The coagulation disorders triggered by endotoxemia result in significant thrombotic tendencies or, in the end stages, bleeding tendencies. The increased pro-coagulant activity induced by endotoxemia can result in catheter problems or in intestinal thrombosis. Sodium heparin is used to prevent these complications at a dosage of 20 to
40 IU/kg every 8 hours. Although a higher dosage of sodium heparin (80 IU/kg) was shown to improve hypotension after colonic detorsion, such a dosage should be used with caution in postoperative cases, since significant hemorrhage can result. Calcium heparin may also be administered at a dosage of 150 IU/kg subcutaneously (SC), followed by 125 IU/kg every 12 hours for six doses and then 100 IU/kg every 12 hours after the seventh dose. Aspirin, a thromboxane inhibitor, has been recommended to prevent platelet aggregation and decrease thrombus formation. However, an in vitro study concluded that equine platelet aggregation induced by endotoxin was mediated by platelet-activating factor and therefore not affected by a thromboxane inhibitor.24

PAIN

Control of pain is an essential component of the management of postoperative patients. Drugs used for pain management should provide a good clinical response while minimally affecting GI motility.

Postoperative pain can originate from peritoneal inflammation, abdominal incision, or intestinal distention. Flunixin meglumine controls postoperative pain and improves the cardiovascular manifestations of endotoxemia. Flunixin meglumine combined with progesterone supplementation may help maintain pregnancy in mares with endotoxemia in the first trimester of gestation. Flunixin meglumine provides analgesia in a dosage-related manner up to a maximal dosage of 1.1 mg/kg. Smaller dosages (0.25 mg/kg) have been shown to improve cardiovascular parameters after endotoxemia.25 Butorphanol is an agonist-antagonist narcotic that can be used to control postoperative pain and at low dosages (0.01 mg/kg) does not affect GI motility. Continuous-rate infusion of butorphanol (13 µg/kg per hour) to horses after celiotomy improved behavior scores and recovery characteristics and decreased plasma cortisol concentration.25 However, time to first passage of feces was delayed significantly in treated horses.25 Therefore, continuous-rate infusion of butorphanol may be contraindicated for certain GI problems. Horses with ileus occasionally require more potent analgesia. In such cases, administration of xylazine, an α2-agonist, may be necessary, even though it can negatively affect GI motility. The duration of analgesia may be prolonged by combined intravenous and intramuscular administration.

Intravenous lidocaine has been advocated for the management of visceral pain. In people, lidocaine is used and has synergistic effects with other drugs. In vitro studies have shown a potential benefit of lidocaine on smooth muscle contraction.26 One clinical study suggested an improvement in small intestinal motility, peritoneal fluid values, and outcome in horses after intestinal surgery; however, the low number of horses with small intestinal lesions makes the value of the results questionable.27 Lidocaine has also been shown to have anti-inflammatory properties and to reduce reperfusion injury in experimental models of ischemia reperfusion.28 One publication reported the use of lidocaine for the management of postoperative ileus in horses, using a loading dose of 1.3 mg/kg IV, followed by an infusion rate of 0.05 mg/kg per minute IV.29 The use of lidocaine is most beneficial with other analgesics and allows the dosage of analgesics to be decreased.

POSTOPERATIVE ILEUS

Adynamic ileus is one of the most commonly encountered complications in horses after GI surgery and is often referred to as postoperative ileus (POI). In horses, POI occurs predominantly after correction of lesions involving the small intestine. Occasionally, POI is seen after correction of large colon problems, primarily large colon volvulus. Intestinal ischemia, distention, peritonitis, electrolyte imbalances, endotoxemia, traumatic handling of the intestine, resection and anastomosis, and anesthesia have all been proposed as potential contributing factors. Risk factors that have been identified for horses developing POI are age greater than 10 years, Arabian breed, PCV greater than 45%, high serum concentrations of protein and albumin, elevated serum glucose, anesthesia for longer than 2.5 hours, surgery longer than 2 hours, resection and anastomosis, lesions in the small intestine, and ischemic small intestine.30-32 There is some evidence that performing a pelvic flexure enterotomy (bowel decompression) and intraoperative administration of lidocaine may decrease the risk of developing POI.30,31

In the current literature, the incidence of POI in horses undergoing surgical treatment of colic has been reported to range from 10% to 21%.30-33 As expected, the survival rate was lower for horses that developed POI than for those that did not develop POI (87% and 84.1% survival rates in horses with POI, versus 93% and 94.1% survival rates in horses without POI). This is a marked improvement over a previous study, which reported a mortality rate of 86% in horses with POI.34 Although management and prognosis of these cases has improved, POI is still associated with 38% to 40% of all postoperative deaths in horses treated for colic.31,32

Disruption of propulsive motility results in the sequestration of fluid, gas, and ingesta in the segment of the GI tract that is dysfunctional and in the intestine proximal to the dysfunctional area. Since small intestine strangulating lesions are the most common problems leading to POI, the distention occurs primarily in the small intestine and stomach. With colitis, endotoxemia, or ischemia following a large colon volvulus, distention may occur in the cecum and large colon. Signs of ileus are progressive and directly related to the accumulation of gas and fluid within the GI tract. Gastric distention usually occurs within 12 to 48 hours after recovery from anesthesia as fluid and gas back up from the small intestine. With increasing GI distention, the animal becomes more depressed and shows signs of increasing abdominal pain such as pawing, flank watching, lying down, and rolling.35-37 Borborygmi are usually decreased or absent. The heart rate is usually elevated as a result of pain associated with distention. Hemoconcentration is reflected by increases in the PCV and total protein, as well as in elevated heart rate and increased capillary refill time. Decreases in plasma chloride and potassium are the most commonly observed electrolyte abnormalities, although sodium and calcium may also be low.34-37 Rectal examination, ultrasonography, and abdominal radiography (in foals) can aid in determining if the small intestine or large
intestine is involved. Nasogastric decompression often requires from 3 to 10 L of fluid. The response to nasogastric decompression provides an important clue that the problem is functional (i.e., POI). After decompression, the horse should show improvement, with decreased pain and heart rate. If no alleviation of signs is observed after repeated attempts at decompression, careful thought should be given as to the likelihood that the problem may be mechanical, such as a complication with the anastomosis, and not a functional POI.

Supportive Therapy
Because of the therapeutic limitations of available prokinetic agents (discussed later), the hallmark of treatment of POI in the horse is supportive therapy. Included in this supportive therapy are fluid, acid–base, and electrolyte therapies. Antibiotics are also indicated if there is compromised intestine or the possibility of bacterial contamination resulting in peritonitis. Along with fluid therapy, nasogastric decompression remains the primary method to treat POI in the horse. Questions concerning when to place the tube, whether the tube should be left in place, and when to start feeding have not been adequately investigated. A study in normal horses indicated that leaving a nasogastric tube in place increases the rate of gastric emptying over a 24-hour period (T. Lammers, Texas A&M University, unpublished data). The clinical significance of this finding in the postoperative horse is unknown. In humans, eliminating or decreasing routine nasogastric intubation with early return to enteral feeding has been shown to be safe and may actually reduce the duration and severity of POI in the horse. This has yet to be substantiated.

Prokinetics
It is logical to assume that during POI in the horse, an imbalance of factors controlling excitation and inhibition of GI smooth muscle occurs. Historically, pharmacologic modulation of GI motility in the horse has been directed at increasing excitatory cholinergic activity with administration of parasympathomimetic agents such as bethanechol or neostigmine, or blocking inhibitory sympathetic hyperactivity with α-adrenergic blockers such as yohimbine and acepromazine.41-43 In addition to being affected by sympathetic and parasympathetic input, contractility of gastrointestinal muscle is directly mediated by enteric inhibitory neurotransmitters such as vasoactive intestinal peptide, adenosine triphosphate, and nitric oxide, and enteric excitatory neurotransmitters such as substance P and acetylcholine.44-47 It is likely that abnormalities involving the enteric nervous system and its neurotransmitters, as well as insult to the enteric smooth muscle cells and interstitial cells of Cajal (astrocytes), which are responsible for generating patterns of electrical activity in the enteric smooth muscle cells that mediate contractile activity, are also involved in the pathophysiology of POI.48-51 At this time, treatment of POI in the horse is limited to pharmacologic agents that influence only a small number of the mediators of motility. This most likely contributes to the limited response seen.

Prokinetics are used for the treatment of POI in the horse. The following is a summary of some of the more frequently used prokinetics in horses.

**Bethanechol**
Bethanechol chloride is a muscarinic cholinergic agonist that stimulates acetylcholine receptors (M2 receptors) on GI smooth muscles or at the level of the myenteric plexus, causing gastrointestinal contractile activity.52 In an equine POI model, bethanechol (2.5 mg SC at 2 and 5 hours postoperatively in ponies) shortened transit time as measured by the passage of beads, and reduced the time until normal activity levels returned throughout the GI tract when administered in combination with yohimbine, an α-adrenergic receptor blocker.53 This drug combination, however, was not as effective as metoclopramide in restoring coordinated gastroduodenal motility patterns in these ponies. Although efficacy in treating motility dysfunction has been questioned in the horse and other species, the prokinetic effects in normal horses and the clinical impression of its benefit in treating horses with ileus provides some support for its use in the treatment of certain motility dysfunctions such as POI and gastric and cecal impactions.41,47,52 The recommended dosage is 0.025 mg/kg IV or SQ, every 4 to 6 hours. The most common side effects of bethanechol are salivation with abdominal cramping and diarrhea.

**Neostigmine**
Neostigmine methylsulfate is a cholinesterase inhibitor that prolongs the activity of acetylcholine by retarding its breakdown at the synaptic junction. In studies on normal horses, the effects of neostigmine (0.022 mg/kg IV) varied depending on the portion of the gastrointestinal tract examined.41,52,53 Neostigmine was shown to delay gastric emptying and decrease propulsive motility in the stomach and jejunum but to increase propulsive motility in the pelvic flexure.53 These results suggest that the drug would not be appropriate for gastric and small intestinal problems but may be beneficial for large intestinal motility dysfunction. However, neostigmine increased the amplitude of rhythmic contractions in both the resting and distended jejunum in anesthetized ponies, and it induced contractile activity in the ileum and increased the rate of cecal emptying in other studies, supporting its use for motility dysfunction in both small and large intestine.52,54 There has been no consensus as to the recommended use of this drug for treatment of motility disorders in horses. It is rarely used as a prokinetic agent in humans.47 There is anecdotal support that neostigmine can reduce the severity of POI in horses, particularly if the large colon is involved. However, its use for impaction colic or in cases with excess GI distention has not been recommended by some authors because of the apparent force of drug-induced contractions.52 The dosage used clinically is 0.0044 mg/kg (2 mg per adult horse) SC or IV, repeated in 20 to 60 minutes. If there is no response and
the horse is not exhibiting any side effects, the amount can be increased by 2-mg increments to a total of 10 mg per treatment. A side effect commonly seen with this drug is abdominal pain.

**Acepromazine and Yohimbine**

Acepromazine and yohimbine are both α-adrenergic antagonists. Their use is based on the assumption that sympathetic hyperactivity contributes to POI. Afferent stimulation during surgery is thought to activate inhibitory sympathetic efferents. Norepinephrine released by post-synaptic sympathetic neurons at the enteric ganglia inhibits the release of the excitatory neurotransmitter acetylcholine by stimulating α1-receptors located presynaptically on cholinergic neurons. Elevated serum catecholamines that can last for the duration of POI have been associated with increased synthesis of norepinephrine in the bowel wall in humans after laparotomy.45,55

Acepromazine maleate facilitates small intestinal transit in normal ponies.54 On the basis of clinical impression, acepromazine administered at 0.01 mg/kg intramuscularly (IM) intraoperatively and then every 4 hours is thought to reduce the severity of POI in horses with small intestinal lesions. Because acepromazine is a nonselective α-blocker that can produce hypotension through α1-receptor antagonism, the animal should be well hydrated before the drug is administered.

Yohimbine hydrochloride is a competitive antagonist that is selective for α2-adrenergic receptors. When administered at 0.15 mg/kg IV at 1, 4, 7, and 10 hours postoperatively in an experimentally induced POI model, it reduced the severity of POI, especially when combined with bethanechol.42 Yohimbine administered at 75 μg/kg was demonstrated to attenuate some of the negative effects that endotoxin has on propulsive motility.57 Since yohimbine is a selective α2-adrenergic antagonist, it should not produce the hypertensive response seen with acepromazine.

**Metoclopramide**

Metoclopramide is a first-generation substituted benzamide whose prokinetic activity is both through dopamine 1 (DA1) and 2 (DA2) receptor antagonism and through 5-hydroxytryptamine 4-receptor (5-HT4) agonism and 5-HT3 receptor antagonism.41,47,58 Stimulation of DA2 receptors inhibits the release of acetylcholine, whereas stimulation of 5-HT4 receptors enhances the release of acetylcholine from the myenteric ganglia.47 Metoclopramide has been shown to stimulate in vitro contractile activity of circular muscle from the stomach and small intestine in the horse.59 In a POI model in ponies, metoclopramide was more effective in restoring GI coordination than adrenergic antagonists and cholinomimetics used individually or in combination. In horses, metoclopramide is most commonly administered at a dosage of 0.25 mg/kg, diluted in 500 mL of saline, IV over 30 to 60 minutes. In a retrospective study, metoclopramide administered as a continuous infusion (0.04 mg/kg per hour) decreased the total volume, duration, and rate of gastric reflux when used prophylactically after small intestine resection and anastomosis.59 Metoclopramide may cause extrapyramidal side effects such as excitement, restlessness, sweating, and abdominal cramping.

**Cisapride**

Cisapride is a second-generation substituted benzamide, which until recently was the most popular and effective prokinetic in human medicine.47 Although it has been taken off the human market because of its cardiototoxic effects, it is discussed here because it is still available through some compounding agencies, and drugs with similar mechanisms of action will soon be available.60 Cisapride functions as an indirect cholinergic stimulant by selectively enhancing the release of acetylcholine from postganglionic neurons in the myenteric plexus.60,62 Unlike that of metoclopramide, the main prokinetic activity of cisapride appears to be mediated through 5-HT4 receptor agonism and 5-HT3 receptor antagonism and not through dopamine antagonism.63 In the horse, cisapride has been shown to act partly through a noncholinergic effect mediated by 5-HT2 receptors.26 In experimental studies and in clinical trials in humans, cisapride’s prokinetic effects were consistently equal to or superior to those of metoclopramide and of domperidone, a dopamine antagonist used as a prokinetic in humans.62,64 In normal horses, cisapride augments the amplitude of gastric contractions, stimulates jejunal activity coordinated with gastric contractions, enhances contractile activity of the large and small colon, and stimulates coordinated activity in the ileocolocolonic junction.64,65,66 In a clinical trial in horses, cisapride (0.1 mg/kg IM every 8 hours) significantly decreased the incidence of POI.57 There are conflicting data on its efficacy for correcting motility dysfunction caused by endotoxin. One study reported no benefit, whereas another suggested that cisapride can attenuate the motility dysfunction induced by endotoxin.58 Cisapride suspended in saline and administered per rectum is very poorly absorbed, and suspended in dimethyl sulfoxide (DMSO), it is inconsistently absorbed.69 Recent work has determined that mixing 400 mg of cisapride with 10 mL of tartaric acid and heating at 50°C for 20 minutes, then adding sterile water to bring the volume to 100 mL and mixing for another 20 minutes at 50°C, followed by sterilizing by filtration, consistently yields a 3-mg/mL solution for IV administration. This should be administered at 0.1 mg/kg every 8 hours.

A recent report has shown that levosulpride, a new substituted benzamide with dopamine (D2) receptor antagonist activity as well as 5-HT4 receptor agonist and 5-HT3 receptor antagonist activity, is as effective as cisapride in treating dysmotility in humans.70 Prokinetics such as levosulpride, and drugs with similar activity, such as tegaserod and prucalopride, are currently replacing cisapride.71

**Erythromycin**

Erythromycin is a macrolide antibiotic with recognized GI side effects. Erythromycin is a motilin agonist that influences motility partly by acting on motilin receptors on smooth muscles. Motilin is a hormone that is released by enterochromaffin cells and stimulates contractile activity in the stomach and small intestine. Motilin infusion in the
horse causes strong contractions in the proximal jejunum in vivo.46 Erythromycin also acts on enteric cholinergic neurons through motilin and/or 5-HT3 receptors to stimulate the release of acetylcholine.47,72 Motilin and erythromycin have been shown to initiate phase III of the migrating motor complex.73 When administered at subtherapeutic antimicrobial levels, erythromycin has been shown to stimulate gastric emptying, antroduodenal coordination, and phase III activity in the duodenum in humans and laboratory animals.73

The dosage that has been used clinically in horses is 1.0 mg/kg in 1 L of saline infused over 60 minutes, every 6 hours. In normal horses, a dosage of 1 mg/kg is effective in stimulating both cecal and small intestinal contractile activity.74 Dosages higher than 10 mg/kg can potentially disrupt propulsive activity. The prokinetic response may diminish with repeated treatments. Erythromycin can downregulate motilin receptors, which would explain this desensitization. Although the recommended prokinetic dosage is supposed to be below the effective antimicrobial level, there have been some anecdotal reports of severe colitis associated with its use, making many clinicians reluctant to use it. In support of this clinical impression, an association between low-dose erythromycin (1.25 mg/kg PO every 8 hours) and Clostridium difficile colitis was demonstrated in one report.75 Erythromycin has been commonly used to treat gastrointestinal disorders in humans, but many of the prokinetic therapeutic benefits that were anticipated have failed to materialize.

**Lidocaine**

Intravenous lidocaine shortens the duration of paralytic ileus in the colon in humans after abdominal surgery.76 Sympathetic inhibitory spinal and prevertebral reflexes are involved in the pathogenesis of POI.45 Lidocaine may act by (1) reducing the level of circulating catecholamines by inhibition of the sympathoadrenal response, (2) suppressing activity in the primary afferent neurons involved in reflex inhibition of gut motility, (3) stimulating smooth muscles directly, and (4) decreasing inflammation in the bowel wall through inhibition of prostaglandin synthesis, inhibition of granulocyte migration and their release of lysosomal enzymes, and inhibition of free radical production.74 Lidocaine causes an in vitro increase in contractility of the circular muscle from the proximal duodenum of horses.26 In a clinical trial in horses, lidocaine was effective in decreasing the duration of reflux in horses with POI and in horses with duodenitis–proximal jejunitis.77 In a retrospective study, intraoperative administration of lidocaine appeared to decrease the risk of POI.78

The recommended protocol requires an initial bolus of 1.3 mg/kg IV administered slowly over 5 minutes, followed by 0.05 mg/kg per minute in saline or lactated Ringer’s solution over 24 hours.29 Side effects include muscle fasciculations, trembling, and ataxia.

**Anti-Inflammatory and Analgesic Therapy**

Recentely, a large body of evidence has accumulated to indicate that motility disorders such as POI and ileus associated with enteritis or colitis are, in part, mediated by an inflammatory cell infiltrate into the intestinal wall.77-79 Intestinal manipulation, lipopolysaccharide administration, and ischemia/reperfusion injury have all been shown to produce significant decreases in in vitro contractile activity of jejunal smooth muscle. In experimental animals, blocking this influx of leukocytes by antiadhesion antibodies eliminates the disruption of motility, supporting a cause-and-effect relationship between intestinal inflammation and POI.77 Intestinal distention, ischemia, and trauma inflicted during decompression or during resection and anastomosis induce inflammation in the bowel wall, with production of inflammatory mediators such as prostacyclin, PGE2, and TNF.

Endotoxemia, associated with necrotic intestine, also stimulates production of inflammatory mediators. Infusions of endotoxin, PGE2, and TNF have been shown to disrupt normal motility.77,78 Both phenylbutazone and flunixin meglumine were shown to significantly attenuate the disruption of gastric, small intestine, and large colon motility elicited by endotoxin infusion.77,80 Administration of these nonsteroidal drugs decreases the production of inflammatory mediators that directly inhibit smooth muscle contractility, while reducing postoperative pain and thus attenuating potential inhibitory sympathetic reflexes. On the basis of these observations, nonsteroidal anti-inflammatory drugs (NSAIDs) are recommended for prevention and treatment of motility disorders associated with GI inflammation.

Besides NSAIDs, adrenergic agonists and opioids are the other two classes of drugs commonly used in horses to control pain associated with colic. Xylazine and detomidine are α2-adrenergic agonists that may inhibit presynaptic acetylcholine release in the myenteric plexus, resulting in a decrease in motility.81 In the horse, xylazine and detomidine have been shown to decrease motility as measured by myoelectrical activity of the distal jejunum, pelvic flexure, cecum, and right ventral colon, and to decrease cecal emptying based on radiolabeled markers.41,52,81-83 However, in another study, xylazine was not thought to seriously disrupt gastrointestinal motility.84 Opioid agonists should be avoided if possible, as they have been shown to depress motility in most species studied.82,85,86 Naloxone, an opioid antagonist, has been suggested by some investigators to be a potentially beneficial drug for treating motility disorders.85 There is some evidence that naloxone may enhance progressive motility in the horse; however, it has also been shown to cause diarrhea and colic in the horse.87 Butorphanol tartrate, an opioid agonist-antagonist, has been shown to inhibit myoelectrical activity in the jejunum, whereas it has no effect on pelvic flexure activity.88 Butorphanol prolonged xylazine-induced inhibition of myoelectrical activity of the cecum and right ventral colon in one study, whereas it produced no undesirable effect on antroduodenal activity in another study.8,84

**Prognosis**

The prognosis for resolution of POI is favorable.31,33 Although this discussion has been limited to pharmacologic interventions, good surgical technique and appropriate aftercare, including fluid and electrolyte replacement, antibiotic and analgesic therapy, and nasogastric decompression, are critical to the outcome of these cases. Because
of the intensive postoperative medical management of these cases, successful treatment is often costly. Frequently, the limiting factor in determining the outcome is the economic constraint imposed by the owner.

**ADHESIONS**

Peritoneal adhesions are one of the most frequent complications seen after colic surgery in horses. Adhesions occur more frequently after surgery for lesions involving the small intestine, and they cause postoperative signs of pain and intestinal obstruction in as many as 22% of these horses.93,97,98 Adhesions are the second most common reason for repeated laparotomy in horses with GI disease.91 Foals seem to be more predisposed to development of adhesions than adults.92

Adhesion formation can be viewed as a variant of the normal physiologic healing process. An intact mesothelial cell layer is critical to the prevention of adhesion formation. Ischemia, distention, drying, or abrasion of the peritoneum during manipulation and decompression of the intestine, as well as hemorrhage, the introduction of foreign material, or infection in the peritoneal cavity, can all result in peritoneal inflammation initiating adhesion formation.93 Once the mesothelial cells are disrupted, the underlying connective tissue containing blood vessels, collagen, lymphocytes, fibroblasts, mast cells, macrophages, and plasma cells becomes exposed. The release of vasoactive substances such as PGE₂, serotonin, bradykinin, and histamine from the exposed submesothelial tissue mediates increased vascular permeability with extravasation of a fibrinogen-rich inflammatory exudate. The release of thromboplastin (tissue factor) and exposure of subendothelial collagen activate both the intrinsic and the extrinsic clotting cascade, leading ultimately to thrombin-mediated conversion of fibrinogen to fibrin, with the fibrin adhering to sites of injury. In the normal healing process, the fibrin tags are lysed by plasmin, and the peritoneal injury is covered within 2 to 5 days by a single layer of mesothelial cells originating from metaplasia of underlying mesenchymal cells, attachment of free-floating mesothelial cells, or transformation of macrophages.94 However, if there is inadequate fibrinolysis, fibroblasts migrate over the fibrin scaffold with neovascularization and produce collagen by day 4, initiating the formation of fibrous adhesions.95

Tissue plasminogen activators are proteases released by mesothelial and endothelial cells that convert inactive plasminogen to plasmin, an important part of the fibrinolysis pathway. After peritoneal injury from mechanical trauma, ischemia, inflammation, or bacterial infection, plasminogen activator activity is decreased. This was thought to occur because of damage to the cells producing plasminogen activator.96 A more recent finding suggests that there is an increased production of plasminogen activator inhibitor, which reduces the level of plasminogen activator activity.93,97,98 Extensive damage to either the parietal or the visceral peritoneal surface tips the balance in favor of adhesion formation, first by increasing the extent of fibrin formation and deposition and second by decreasing fibrinolytic activity.

Several strategies are currently being used to prevent or minimize adhesion formation. The most important one involves minimizing trauma by paying attention to good surgical technique, such as keeping the bowel moist at all times, providing adequate hemostasis, leaving as little suture material as possible exposed, removing as much damaged tissue as possible, and handling the tissue as gently as possible. Trauma is also reduced by making the decision to perform surgery in a timely manner. Both ischemia/reperfusion and intraluminal distention and decompression have been shown to cause severe changes in the seromuscular layer of the small intestine, such as serosal edema, leukocyte infiltration, and erythrocyte leakage with fibrin accumulation, whereas a similar insult to the ascending colon does not result in comparable seromuscular lesions.95,99 Prophylactic strategies include intervention in the inflammatory, coagulation, and fibrinolysis cascades with anti-inflammatory or heparin therapy, and using therapies that provide mechanical separation of the injured areas.

Perioperative NSAIDs and antibiotics are used routinely during GI surgery. Because both inflammation and infection may predispose to adhesion formation, this combination of chemotherapeutic strategy should curtail the production of adhesions. Broad-spectrum antibiotics should be administered prophylactically or therapeutically, depending on the degree of compromise to the affected segment of bowel. NSAIDs are continued after surgery for 3 to 5 days to reduce the inflammatory response. DMSO (20 mg/kg IV twice a day for 72 hours) may also reduce inflammation. There is experimental evidence that this combination of anti-inflammatory and antimicrobial therapy is effective in reducing adhesion formation in horses.100,101 In a recent experimental study of ischemia-induced adhesions in foals, administration of flunixin meglumine and antibiotics or administration of DMSO appeared to be more effective than 3% sodium carboxymethylcellulose or heparin in preventing the formation of adhesions.102 It is interesting to note that a 3% solution was used in this study, compared with the 1% solution in studies discussed later in this chapter.

Heparin is composed of a family of naturally occurring sulfated glycosaminoglycans that are synthesized by connective tissue mast cells.103,104 By binding to AT-III, a glycoprotein synthesized in the liver and vascular endothelium, heparin markedly enhances the rate of AT-III–mediated inactivation of clotting factors (factors IX, X, XI, and XII and thrombin).105,106 The AT-III–heparin complex, by neutralizing thrombin, suppresses thrombin-mediated amplification of the coagulation cascade and inhibits thrombin-mediated conversion of fibrinogen to fibrin.107 Heparin sodium (40 IU/kg IV intraoperatively, followed by 40 IU/kg SC twice a day for 2 days) decreased adhesion formation in ponies after experimentally induced intestinal ischemia.108 Based on pharmacokinetic studies using calcium heparin instead of sodium heparin, an initial dose of 150 IU/kg SC followed by 125 IU/kg SC twice a day for six doses and then 100 IU/kg SC twice a day is recommended to maintain therapeutic anticoagulant levels.109 Some evidence suggests that calcium ions inhibit the heparin–AT-III–thrombin reaction. Consequently, a higher dosage of calcium heparin than sodium heparin is required to reach therapeutic levels,108 although this finding is questioned.109

Plasma AT-III levels are reported to be decreased in some horses with abdominal disease.100,101 Because heparin acts as a cofactor to AT-III, heparin therapy would be of limited value if peritoneal AT-III were depleted significantly. However, changes in plasma AT-III levels do not always
correlate with changes in peritoneal levels.\textsuperscript{8,12} Peritoneal AT-III levels have actually been found to be increased in some horses with colic.\textsuperscript{11,13} The most common complication reported with heparin therapy in horses is anemia induced by erythrocyte agglutination.\textsuperscript{24}

Intraperitoneal sodium carboxymethylcellulose (SCMC) is effective in preventing adhesions in experimental models using laboratory animals, and there is evidence to support its efficacy in the prevention of experimentally induced adhesions in horses.\textsuperscript{15,16} The proposed mechanism of action is the “siliconizing” effect that SCMC has on the bowel. This mechanical lubricating barrier minimizes the duration of direct apposition of traumatized tissue, preventing the establishment of fibrin tags between two surfaces, although the effect is most likely transient, because the SCMC is cleared rapidly from the abdomen. A 1\% solution of SCMC (7 mL/kg body weight) is infused into the peritoneal cavity through a sterile stallion catheter before tying the last suture in the linea alba.\textsuperscript{17} No adverse effects on abdominal incisional wound healing were observed in horses treated with SCMC.\textsuperscript{18} In several experimentally induced adhesion studies, horses treated with 1\% SCMC had reduced frequency of intra-abdominal adhesions compared with controls.\textsuperscript{18,19}

Sodium hyaluronate (HA) has also been used by itself and in conjunction with SCMC to reduce adhesions. Application of a 0.4\% HA solution to the serosal surface of the jejunum significantly decreased the incidence of experimentally induced intra-abdominal adhesion formation in ponies, whereas SCMC did not significantly reduce adhesions.\textsuperscript{20} A bio-resorbable hyaluronate-carboxymethylcellulose membrane that is applied over an anastomosis site or an area of localized trauma has also been shown to be beneficial in reducing adhesion formation.\textsuperscript{21,22}

Intraperitoneal instillation of crystalloid solutions is often used to prevent adhesion formation, but conflicting results have been reported regarding their efficacy.\textsuperscript{23} The proposed mechanism is hydrodisplacement of the abdominal organs. However, large volumes of fluid in the peritoneal cavity may compromise the host’s ability to fight infection by interfering with opsonization and phagocytosis.\textsuperscript{24} An alternative approach is the use of peritoneal lavage, which should remove fibrin and other inflammatory mediators while providing mechanical separation of the bowel at the time of lavage. Standing postoperative peritoneal lavage significantly reduced the number of adhesions in horses that received two peritoneal lavages for 2 days postoperatively with 10 L of lactated Ringer’s solution delivered through a 32-French chest trocar inserted in the abdomen during surgery.\textsuperscript{25} Another technique for abdominal drainage is through the use of a closed suction intra-abdominal drain with intermittent peritoneal lavage. This technique has been associated with a high incidence of minor complications such as partial obstruction of the drain (26\%), leakage of fluid around the drain (16\%), and subcutaneous fluid accumulation (12\%).\textsuperscript{26}

**SURGICAL COMPLICATIONS**

Significant complications, such as hemoperitoneum or peritonitis, may result from surgical procedures. Abdominal surgical procedures must adhere to basic principles of good surgical practice (after Halsted), including accurate homeostasis, gentle tissue handling, approximation of tissue, obliteration of dead space, minimal contamination, accurate ligation, and minimal foreign material. Postoperative hemorrhage can result from ligature slippage or from mucosal hemorrhage following intestinal resection and anastomosis. Fatal hemorrhage resulting from tearing of the portal vein or, less commonly, the caudal vena cava has been reported after manual reduction of epiploic foramen entrapment.\textsuperscript{27}

Therefore, reduction of an epiploic foramen entrapment should be performed with one hand on each side of the foramen and gentle feeding of the entrapped bowel through the foramen in a horizontal direction, because pulling the bowel in an upward direction may lead to tearing of the previously mentioned major vessels. Hemorrhage has also been reported as a complication of enterotomies, particularly those performed in the large colon. Therefore, in these locations, a full-thickness suture pattern may be indicated as a first layer.\textsuperscript{28}

Administration of whole blood may be necessary if signs of hemorrhagic shock develop (increased heart rate, pale mucous membranes, weakness, and collapse). Fresh blood collected in plastic bags to preserve platelet activity should be given, as stored blood requires several hours to restore RBC oxygen-carrying capacity. Because signs of hemorrhagic shock develop after loss of 25\% to 30\% of blood volume, transfusion of 6 to 8 L of whole blood may be required (see Chapter 4).

Complications have been reported that are unique to specific surgical techniques. Small intestinal volvulus may develop after side-to-side anastomosis in ponies. Intussusceptions have been reported after small intestinal surgeries. Jejunojejunal intussusception was reported after a stapled functional end-to-end anastomosis in two pony mares\textsuperscript{29} and in two ponies after inverting closure of small intestinal transverse enterotomies,\textsuperscript{30} suggesting that excessive cuff formation should be avoided during small intestinal closure. Chronic intermittent colic with small intestinal distention can occur after functional end-to-end jejunojejunalostomies. Significantly dilated anastomoses found on re-laparotomy may hinder the passage of the peristaltic wave and are related to excessive length of the anastomosis.

Internal herniation is a possible complication of small intestinal resection, and care should be taken to obliterate all possible internal spaces. Closure of the ileocecal fold after jejunocecostomy, mesenteric closure after small intestinal resection or ileocolostomy, and closure of potential spaces after intestinal bypass are recommended to avoid this problem.\textsuperscript{31,32}

Extensive small intestinal resection (greater than 60\%) has been associated with malabsorption, diarrhea, weight loss, and liver damage in ponies.\textsuperscript{33} In a separate study, a short-interval feeding program (pelleted ration divided into eight feedings per day) prevented the development of a clinical malabsorptive syndrome after 70\% of small intestinal resections in ponies.\textsuperscript{34}

Jejunoocecostomy procedures are reported to have an increased risk for postoperative complications. An ileocolic intussusception was reported after jejunocecostomy in one horse.\textsuperscript{35} Alterations in calcium absorption and fat absorption and microbial derangements in normal flora have been suggested as potential complications. Attaching
the jejunum as close to the base of the cecum as possible decreases backflow pressure, discouraging fluid ingesta in the cecum from traveling orally back into the jejunum.

Ileal impactions may recur in the immediate postoperative period, particularly if a bypass procedure was not performed. Horses need to be fed carefully, using a laxative diet, to avoid this complication.

There is a 15% recurrence rate reported for large colon displacements and torsion. Factors contributing to recurrence have not been thoroughly identified. Recurrence of large colon displacements can be prevented by colopexy and large colon resection. Colopexy of the large colon has been reserved for nonperformance animals because of reported intestinal rupture after colopexy.136 Extensive large colon resection is associated with short-term decreased absorption of water, decreased absorption of phosphorus, and weight loss.139 Horses that have undergone large colon resection therefore have increased requirements of water, phosphorus, and better-quality protein.

Recurrence of small colon impaction is also a problem. Surgical evacuation of the large colon is recommended after surgical correction of small colon impactions. These horses should be managed with a laxative diet in the immediate postoperative period.

Management of postoperative complications may require repeat celiotomy. Clinical signs indicating the need for repeat celiotomy include persistent abdominal pain despite successful gastric decompression, marked and progressive intestinal distention, systemic deterioration associated with degenerative changes in the abdominocentesis, and presence of bacteria. In one study, 8.2% of horses (53 of 648) were subjected to repeat celiotomy. The long-term outcome of horses subjected to a second surgery was significantly worse than that of horses undergoing a single surgery.

SEPTIC PERITONITIS

Septic peritonitis is one of the most frequent fatal postoperative complications following exploratory laparotomy in horses (other common fatal complications are adhesions and ileus).140,141 In one study, 56% of horses with septic postoperative peritonitis did not survive.142 Postoperative peritonitis may result from necrosis of a segment of the GI tract before or after surgical intervention, contamination occurring at surgery, or leakage from the anastomosis or enterotomy site. In response to bacterial contamination, peritoneal macrophages and mast cells release histamine and prostaglandins, leading to vasodilatation and increased permeability of the peritoneal vessels. The subsequent peritoneal exudate contains fibrin, complement, immunoglobulins, and clotting factors. Chemotaxins such as IL-1, leukotriene B₄, and TNF produced by activated macrophages, mast cells, and neutrophils stimulate a further influx of neutrophils, exacerbating the inflammatory response.143,144 Bacteria and other particles can be cleared from the peritoneal cavity through the diaphragmatic lymphatics. Movement of the diaphragm during respiration facilitates the uptake of peritoneal fluid into stomata, which are intercellular gaps between mesothelial cells covering the diaphragm. The stomata communicate with lymphatic lacunae, which drain peritoneal fluid into the subternal lymph nodes and subsequently via the thoracic duct into the bloodstream. Systemic effects from peritonitis may be initiated by the entrance of bacteria into the bloodstream, by the action of inflammatory mediators produced by macrophages and neutrophils, or by absorption of endotoxin from the peritoneal cavity into the portal venous system, which then acts on the Kupffer cells of the liver, contributing to the septic response.145

Clinical signs commonly associated with peritonitis include mild colic, depression, anorexia, ileus, diarrhea, fever, tachycardia, and tachypnea.142,144,146 Besides relying on clinical signs, the diagnosis of peritonitis is based on peritoneal fluid analysis. Peritoneal fluid from normal horses has a nucleated cell count of less than 5000 cells/µL and a protein concentration of less than 2.5 g/dL. However, after an exploratory laparotomy, the peritoneal nucleated cell count, percentage of neutrophils, fibrinogen, and protein concentration become markedly elevated.144,145 The mean nucleated cell count peaks at approximately 200,000/µL at day 4 and remains elevated at 40,000/µL through day 6; the mean protein concentration remains elevated and peaks at 6 g/dL on day 6 after an exploratory laparotomy. Therefore, absolute values and differential counts may not provide sufficient information on which to base a diagnosis of postoperative septic peritonitis. Hence, cytologic evaluation of the peritoneal fluid is crucial for a definitive diagnosis. Toxic or degenerative changes in neutrophils and the presence of intracellular or extracellular bacteria are indicative of septic peritonitis. Peritoneal pH and peripheral and peritoneal glucose may also be evaluated to diagnose septic peritonitis. A serum-peritoneal glucose difference greater than 50 mg/dL or a peritoneal pH less than 7.2 with a peritoneal glucose of less than 30 mg/dL is highly suggestive of septic peritonitis.148 Peripheral blood values determined by complete blood count and fibrinogen should be compared with peritoneal fluid. A left shift, thrombocytopenia, or hypo-proteinemia is also indicative of septic peritonitis.147,149 Peritoneal fluid should be submitted for both aerobic and anaerobic cultures and sensitivity.

Treatment should be directed first toward stabilization of the animal and then toward the inciting cause. IV fluids should be administered to correct dehydration and acid-base and electrolyte abnormalities. Patients are often hypoproteinemic (total protein less than 4.4 g/dL) and require plasma. If sepsis is caused by gram-negative bacteria, administration of hyperimmune serum (Polymune, Veterinary Dynamics, San Luis Obispo, Calif; and Endoserum, IMMVAC, Columbia, Mo) may attenuate the degree of endotoxemia. Flunixin meglumine (0.25 mg/kg IV three times a day) attenuates symptoms of endotoxemia. Broad-spectrum IV antibiotics are imperative. The most common organisms isolated from horses with peritonitis include the aerobic bacteria E. coli, Staphylococcus, Streptococcus, and Rhodococcus equi and the anaerobic bacteria Bacteroides, Clostridium, and Fusobacterium.142,145,146 If necrotic intestine or leakage of an anastomosis or enterotomy is considered to be the cause of septic peritonitis, a second exploratory laparotomy is indicated.

Open peritoneal drainage has been described for the treatment of mild inflammatory peritonitis in an experimental model in horses,150 but the efficacy of this technique in clinical septic peritonitis is not known. However, peritoneal lavage is an important component of the treatment
INCISIONAL COMPLICATIONS

Incisional complications after exploratory celiotomy in horses include infection, dehiscence, suture sinus formation, and herniation. The frequency of incisional infections in horses after colic surgery is 10% to 37%. A frequency of 28.6% was reported after one colic surgery, and 87.5% after two or more celiotomies. Predisposing factors for incisional complications include repeat celiotomy, increased duration of surgery, use of a near-far-far-near pattern, use of chromic gut, leukopenia, incisional edema, postoperative pain, weight (greater than 300 kg), and older age (older than 1 year). Incisional hernias are reported in 13% to 16% of horses after celiotomy. The single most important risk factor for herniation is incisional infection, which had a relative risk of 17.8 for causing herniation.

Horses developing incisional infections are initially febrile without any localizing signs. Excessive tenderness and edema are sometimes noted. Most incisional infections develop 3 days or more after surgery, and drainage can sometimes be delayed up to 14 days. Systemic antibiotics delay the onset of drainage. Once drainage is noted, it is important to provide a route for exudation by removing a few staples or sutures at the site of the drainage. Culturing of the drainage identifies potential hospital problems. Horses that are febrile after drainage has been established and in which excessive edema or cellulitis is not evident do not require systemic antibiotics. However, fever and significant tissue reaction are indications for antibiotic therapy. Flushing of the wound should be performed with caution, because it can propagate the infection along the entire incision line. An abdominal support should be provided, because dehiscence may occur.

Incisional infection rates can be decreased by shortening surgery time, using adequate draping, isolating any enterotomy incision from the clean surgical field, and minimizing trauma to the incision during exploration of the abdomen. A plastic ring drape can be used to protect the incision and is preferred by some surgeons for all exploratory surgeries. Bacterial culturing of the wound does not have predictive value for the incisional infection rate. Closure of the linea alba should be performed with a suture material that is minimally reactive. Chromic gut has been associated with increased incisional drainage in horses, and braided non-absorbable suture may cause suture sinus formation. Suture patterns do not particularly influence incisional infection rate, although in one study, a near-far-far-near pattern was associated with increased postoperative drainage. Care should be taken, however, not to take overly large bites and to avoid excessive force when tightening sutures, since this can lead to ischemia, predisposing to incisional infection.

If incisional infection is present, or in cases of repeat laparotomy in the presence of an infected incision, the wound can be apposed with large stainless steel tension-releasing sutures, placed distant from the incision, which help support the abdominal wall (see Chapter 38). The linea alba is closed, and the subcutaneous tissues and skin can be left open for drainage. The reported rate of acute incisional dehiscence is low (2.0% to 2.9%), but this is the most serious acute incisional problem and can be fatal. Violent recovery, severe postoperative abdominal pain, prolonged surgery time, and use of a continuous suture pattern in the linea alba have been associated with early postoperative dehiscence. Acute incisional dehiscence is best managed by immediate repair under general anesthesia if the intestine has not been severely traumatized. For details on repair of acute total incisional dehiscence, see Chapter 38.

Incisional herniation is the most significant problem resulting from incisional infection. Incisional hernias do not necessarily require repair if they are small and do not cause deformation in the body wall. Large hernias that protrude from the abdomen require repair for cosmetic reasons but also because they are subject to repeated trauma. Hernias must be repaired only after the incision is healed and free of infection and the hernial ring has gained strength. This usually requires a minimum of 3 months after the original surgery. No skin abrasions, open wound, or drainage should be present at the time of hernia repair, because these may contaminate the surgical site, which could have serious implications, especially if an implant is used to repair the hernia. In preparation for surgery, the horse should be fasted to decrease abdominal weight. If the hernia is large, a complete pelleted feed can be substituted for hay 2 weeks before surgery to further decrease abdominal contents.
The horse is positioned in dorsal recumbency and draped in a routine manner. Three methods of hernia repair are described: primary closure, mesh implantation, and mesh implantation combined with fascial overlay. An elliptic incision is made over the hernial defect, and the excess skin is removed by subcutaneous dissection, leaving the hernia sac intact. At this time, the potential for primary closure of the defect is determined. If this is judged feasible, the hernia sac is removed and the edges of the defect are freshened. A near-far-far-near or cruciate pattern is used to close the defect using a large monofilament nonabsorbable (polypropylene) or slowly absorbable (polydioxanone) suture material.

If excessive tension is of concern with primary closure, a mesh implant can be placed to reinforce closure. The hernia sac is left in place, and the mesh is trimmed to fit the defect. The mesh is inserted over the hernia sac and deep to the abdominal wall (retroperitoneally). Vertical mattress sutures of a large monofilament material (polypropylene or polydioxanone) are used to suture one side of the mesh to the body wall. The same material and patterns are used to pre-place sutures on the other side, estimating the distance needed to completely close the defect. The sutures are pulled tight. The linea is then apposed with a single-interrupted pattern. When the edges of the linea cannot be apposed, the mesh must be pulled tight to avoid sag and maintain a more cosmetic result. In the fascial overlay technique (see Chapter 38 for details), an elliptic incision is made through all layers on one side of the hernial sac, leaving the base attached. The mesh is implanted deep to the abdominal wall but superficial to the peritoneum and retroperitoneal fat. The edges of the mesh are folded toward the outside or laid flat, to avoid intestinal irritation and possible perforation.

Materials used for hernia repair in horses include polypropylene (Marlex, Davol Inc, Cranston, RI) and plastics (Proplast, Goshen Laboratories, Goshen, NY). The polypropylene is more resilient and may sag more than the plastic implants. Studies in other species indicate

that the inertness of the polyester mesh in the presence
of infection enables wound healing without formation of
persistent abscesses or sinus tracts, but the cost is much
higher. In equine cases of postoperative infection, the
implant may have to be removed to resolve persistent
drainage.

Postoperative care after hernia repair includes mini-
mizing abdominal weight for 2 weeks, stall rest for 4 weeks,
and light exercise for 4 to 6 weeks. An abdominal bandage
may help reduce edema in the initial postoperative period.
All straining should be avoided in the postoperative period.
The most serious complication after mesh repair is infection
of the surgical site. Although systemic antibiotics are some-
times successful in treating the infection, in most cases the
implant has to be removed to eliminate this complication.
When infection develops, recurrence of the hernia may be a
problem.

Recently, a postsurgical abdominal wrap has been advo-
cated for the management of incisional hernias (CM Heal,
CM Equine Products, Norco, Calif). These abdominal band-
ages provide firm even abdominal support, with a special
pocket designed to apply direct pressure over the hernia site
and they are available in different sizes. Anecdotal reports
and the authors’ experience are favorable for healing of
incisional hernias without surgical intervention. An addi-
tional benefit is the ability to start the horse in an exercise
program while the abdominal support is in place. Addi-
tional indications include the need for additional
support after surgery in advanced pregnancies, and correc-
tion of umbilical hernia in foals.

POSTOPERATIVE MONITORING

Principles of monitoring horses after abdominal surgery are
based on restoration of circulating fluid volume, electrolyte
and acid–base equilibrium, and GI function. Table 39-1
summarizes the care of horses after abdominal surgery
based on surgical findings. However, these are only guide-

lines, and therapy should be adjusted to individual cases based on physical and laboratory examination.

As a rule, horses on IV fluid therapy should be observed hourly and their hydration status evaluated every 6 hours by PCV and total protein determination. Horses that had significant bowel damage or ileus should be examined (including body temperature, pulse, respiration rate) every 4 hours until they have stabilized. Creatinine should be monitored daily until values are within the normal range. Postoperative fever is common within the first 24 hours of surgery but should resolve thereafter. A persistent fever should be investigated (impending colitis, peritonitis, catheter sepsis). Small intestinal diseases have a high incidence of postoperative ileus, whereas diarrhea more commonly follows large intestinal disorders. Laminitis is a risk for all horses but is more likely to occur if significant bowel damage was present. For all horses that are at risk for the development of endotoxemia, hyperimmune serum or polymyxin B is administered to bind endotoxin. For all horses that are at risk for the development of laminitis, a systemic (acepromazine) or topical (nitroglycerin) vasodilator is indicated, because these drugs are most effective before the onset of clinical signs of laminitis.

Perioperative antimicrobial agents should be of the broad-spectrum type and should have minimal effects on GI flora—for example, penicillin combined with gentamicin or, if significant elevation in creatinine is present, cephalosporin. Perioperative antibiotic therapy is applied in procedures in which the bowel lumen was not entered, and continues until the horse is afebrile for 24 hours and all systemic parameters have improved after enterotomies or resection and anastomosis procedures. Objective criteria that can be used for the discontinuation of systemic antibiotics include a normal white blood cell count without bands, normal temperature, absence of abdominal discomfort, and return of normal appetite.

Analgesic therapy is indicated after celiotomies. Flunixin meglumine is recommended for a minimum of 24 hours and then as needed, depending on the horse’s systemic condition and comfort level.

In small intestinal disorders, feeding is resumed in small amounts after 12 hours if the horse has not developed reflex. The horse should first be offered water, followed by small amounts of wet hay or fresh grass. In large colon disorders, feeding can be resumed as early as 8 hours after surgery, provided there is good intestinal health. In cases of large colon torsion, feeding is delayed until there is evidence of mucosal integrity. Ileal, cecal, and large and small colon impactions should be closely monitored when feeding is delayed until there is evidence of mucosal integrity. Ileal, cecal, and large and small colon torsion, feeding is delayed until there is evidence of mucosal integrity. Ileal, cecal, and large and small colon impactions should be closely monitored when feeding is resumed, because these animals are at risk for reimpaction. The use of laxatives such as mineral oil is recommended in the immediate postoperative period for impactions. For details on nutritional support for the critical surgical patient, see Chapter 6.

The upper airway has complex physiologic functions including olfaction, phonation, deglutition, thermoregulation, filtering and conditioning of the inspired air, and protecting the lower airway from aspiration. Most important, the upper airway also functions as a conduit for airflow to and from the lung, and, because the horse is an obligate nasal breather, a normal upper airway is critical in this species. To accommodate the many diverse demands placed on it, the upper airway was not ideally designed for any one activity. For example, the equine upper airway has a large dead space volume, it has high resistance to airflow, and it tends to collapse in response to negative pressures generated during inspiration.1-4 Although none of these characteristics is ideal for an airflow conduit, compromises in design are necessary to accommodate the other upper airway functions. For these reasons, the upper airway may well be a limiting factor in the horse’s exercise capacity, and tolerances in the upper airway are minimal. Even the smallest lesion before surgery or remaining after completion of a surgical procedure may further limit performance. This makes surgical interventions in the upper airway challenging, and if upper airway function is not fully considered, surgical outcome is often suboptimal. Consequently, surgeons must have a working understanding of upper airway physiology. The purpose of this chapter is to provide the surgeon with information that should be considered when performing upper airway surgery in the horse.

THE UPPER AIRWAY AND PERFORMANCE

The capacity of horses to increase ventilation in response to the demands of exercise is truly enormous. A normal horse at rest breathing 15 times a minute with a tidal volume of 5 L has a minute ventilation of 75 L. During exercise, respiratory rate and tidal volume increase to achieve a minute ventilation of approximately 1500 L.5 The upper airway must accommodate this 20-fold increase in airflow by undergoing changes in caliber, rigidity, and shape. In spite of these adaptations to exercise, evidence suggests that in exercising horses upper airway resistance becomes a large portion of total respiratory resistance, and this increase in resistance may limit performance.3 In strenuously exercising horses, the PaO₂ decreases and the PaCO₂ increases. This perturbation in gas exchange is in part caused by insufficient alveolar ventilation, although diffusion limitation also plays a major role. Substituting a mixture of helium and oxygen for air reduces airflow resistance, and blood oxygenation is improved.1 Taken together, this is strong evidence to suggest that upper airway resistance limits arterial blood oxygenation in exercising horses, thereby limiting oxygen delivery to tissues and performance. Thus, if the function of the upper airway as a conduit for airflow is taxed to the maximum during exercise in normal horses, it is easy to understand that small upper airway lesions can significantly impact upper airway function during exercise and further affect performance.

MECHANICS OF AIR FLOW

The respiratory muscles, primarily the diaphragm, provide the force needed for ventilation. The pumping action of these muscles results in large pressure changes in the airways. On exhalation, pressure in the upper airway becomes positive, driving the air out against the atmospheric pressure, whereas on inhalation, pressures are negative, resulting in movement of air from the outside to inside the lung. The greater the exercise intensity, the greater are the airflow rates and the larger are the pressure changes. During high-intensity exercise, the pressure in the trachea is approximately 15 cm H₂O on exhalation, and it is −30 cm H₂O on inhalation6 (Fig. 40-1). Positive pressure in the upper airway during exhalation encourages upper airway dilation in this phase of the respiratory cycle. On inhalation, however, the...
negative pressure in the upper airway encourages tissues to collapse, thus narrowing the upper airway (Fig. 40-2).

The ratio of driving pressure and the resulting airflow is called impedance. Impedance is a very useful calculated variable, because it is a measure of how much the airflow is opposed by the respiratory system. One of the most important determinants of impedance is airway resistance. Airway resistance in turn is primarily determined by airway diameter. Many surgically correctable conditions of the upper airway (e.g., recurrent laryngeal neuropathy) narrow the airway lumen, decrease its diameter, and therefore increase impedance.\(^7\) Measurements of upper airway impedance on inhalation and exhalation demonstrate that, even in normal horses, the upper airway is only partially able to withstand these pressure swings, especially during exercise. During inhalation, subatmospheric intraluminal pressures cause the airway to narrow, whereas positive intraluminal pressures enlarge the airway diameter during exhalation. As a consequence, impedance is approximately twice as high on inhalation as it is during exhalation\(^8\) (Fig. 40-3).

At first glance, it may be surprising that upper airway pressure swings are sufficient to cause such large changes in resistance in normal horses. This phenomenon is explained by the observation that small changes in airway caliber cause large changes in resistance. The relationship between resistance (R) of a cylindrical tube with a length (L) and radius (r) is given by the following formula,

\[
R = \frac{8 \times u \times L}{r^4},
\]

where \(u\) is the viscosity of the air. This equation demonstrates that the radius is a very important determinant of resistance, and that reducing the radius by half increases resistance 16-fold. Thus, a relatively small decrease in upper airway caliber can significantly increase resistance to flow and limit performance. Once the cross-sectional area of an airway region is decreased, air velocity increases and intraluminal pressure decreases further. This phenomenon, called the Bernoulli effect, reduces airway cross-sectional area even further, setting up a vicious cycle that results in airway collapse (called dynamic collapse).

**DISTRIBUTION OF AIRWAY RESISTANCE**

In the horse, as in most mammals, upper airway resistance is a significant proportion of total resistance to flow. In the resting horse, a full two thirds of the total resistance to airflow resides in the upper airway.\(^3\) This portion increases during exercise. Because of this, most animal species switch to mouth breathing during exercise, which provides a low-resistance pathway for the greater airflow required during exercise and minimizes the work of breathing. The horse cannot breathe through its mouth effectively, and the approximately 20-fold increase in airflow that occurs during exercise must be totally accommodated by the upper airway. Obligate nasal breathing is the result of a tight seal between the soft palate and the laryngeal cartilages. When the nasal passages are occluded, this seal may be broken and mouth breathing results. However, in the horse, the resistance to airflow through the mouth is apparently very high.

During exercise, the distribution of airflow resistance changes significantly. In the exercising horse, during inhalation, intrathoracic resistance is less than 25% of total resistance to flow and the remaining resistance is almost evenly
divided between nasal and laryngeal resistance. On exhalation, the intrathoracic and extrathoracic resistances are about even.2

The upper airway caliber varies with the region. Airway diameters are smallest at the external nares and larynx and largest throughout the nasal turbinate area and pharynx. This observation has practical implications, because it means that lesions in high-resistance areas (external nares and larynx) are more likely to cause clinically significant upper airway obstruction than similar-size lesions in regions such as the pharynx. For example, a small granulomatous lesion located on the axial surface of the arytenoid cartilage is a concern because it reduces the airway caliber in a region of the upper airway that is already narrow. In contrast, pharyngeal lymphoid hyperplasia is not likely to significantly increase total resistance to airflow, because this space-occupying lesion is located in the pharynx, which has a large cross-sectional area, and therefore the lesion contributes less to airflow resistance.

**STABILIZING THE UPPER AIRWAY**

The upper airway is designed to prevent collapse on inhalation. The simplest way to prevent a tube from collapsing in response to negative intrathoracic pressure is to make the wall rigid. Indeed, for some of its length, the upper airway is rigidly supported by bone and cartilage. In other regions of the airway such as the external nares, pharynx, and larynx, rigid support by bone or cartilage is incompatible with other functions such as swallowing and protecting the lower airways. In these regions, the upper airway is supported by muscular activity. Neural reflexes regulate the activity of upper airway dilator muscles.9-11 On inhalation, these muscles begin to contract just before the diaphragm, and they remain active during inhalation. In this way, the upper airway stiffens before it is exposed to subatmospheric pressures. This phasic activity is finely tuned by pressure- and flow- (temperature-) sensitive receptors in the upper airway that, when stimulated, enhance reflex activation of upper airway dilator muscles. These muscles then provide appropriate tension to prevent dynamic collapse of tissues on inhalation.12,13

**External Upper Airway Support**

Recently, a nasal strip became commercially available as an external nasal dilator. It mechanically supports the soft tissue that forms the lateral wall at the narrowest portion of the nasal cavity (nasal valve), located just rostral to the naso-incisive notch. This region is bound medially by the nasal septum, ventrally by the concha, and dorsolaterally by the skin and dorsal conchal fold. The strip consists of three polyester springs sandwiched between two layers of material, and it adheres to the horse's nose. When the strip is applied, endoscopic examination shows that the strip dilates the nasal valve region.14 Furthermore, in exercising horses, the nasal strip decreases inspiratory impedance.14 Interestingly, the nasal strip also decreases the severity of exercise-induced pulmonary hemorrhage (EIPH).15,16 These findings suggest that in exercising horses, the nasal strip reduces upper airway tissue collapse on inhalation. This would result in decreased inspiratory impedance during exercise, and less negative inspiratory pressures. Less negative inspiratory pressure may reduce the transmural pulmonary capillary pressure. Because excessive transmural pulmonary capillary pressure is responsible for EIPH,17,18 reduction in this pressure very likely accounts for the observed decrease in the severity of EIPH.

**Head Position**

Horses are often required to exercise with their heads and necks in unnatural positions. For example, Standardbred horses are raced with an overcheck, which forces the head and neck into extension. Sport horses, such as dressage horses, commonly exercise with head and neck flexed. Head and neck position significantly affects upper airway impedance.15 In resting horses that are holding their heads in a natural position, the air entering the upper airway turns approximately 90 degrees to flow from the nasal passages into the trachea. This change in direction contributes to the work of breathing. Normally, horses straighten their head and neck during exercise. When the horse's head and neck are flexed, upper airway impedance during exercise is about 50% greater than that of a horse exercising with head and neck in the extended position.19

Straightening of the head and neck not only provides a more direct route to the lung, it also tends to stretch upper airway tissues, making them more rigid and resistant to collapse. It stands to reason, therefore, that dynamic upper airway obstructions, especially those involving the pharynx, are often more apparent when affected horses are exercised with a flexed head and neck position.

**External Nares**

The external nares of the horse are very mobile and can completely close the upper airway (as occurs during swimming) or fully dilate it (e.g., during intense exercise). The external nares and adjacent nasal valve are among the narrowest portions of the upper airway; therefore, lesions in this region significantly affect performance.20 The dilator muscles of the external nares, such as the dilator naris lateralis, and the transversus nasi are innervated by the facial nerve, and horses with facial nerve dysfunction have marked inspiratory airway obstruction during exercise.

**Nasal Turbinate Region**

The nasal turbinate region has convoluted conchae that encourage particle deposition and conditioning of the inspired air. This portion of the upper airway is rigidly supported by cartilage and bone. However, marked changes in airway caliber are possible even in this bone- and cartilage-supported region. The upper airway is lined by mucosa that contains vascular sinuses. The purpose of this extensive vasculature is thermoregulation and humidification of inhaled air. These vessels are potentially very large and have the ability to fill with blood, thickening the upper airway mucosa to the point of occlusion. Normally, the size of capacitance vessels is kept small by tonic sympathetic innervation. During exercise, the sympathetic tone increases, capacitance vessels are constricted, and the airway diameter is increased.25 Injury to the sympathetic trunk innervating
this region—for example, in Horner’s syndrome—can cause complete nasal occlusion of the affected side. Unilateral airway obstruction is often the longest-lasting condition associated with Horner’s syndrome, and it causes significant exercise intolerance. Nasal vascular engorgement also has been identified as a cause of airway obstruction in horses recovering from general anesthesia after removal of the orotracheal tube. This obstruction is sufficiently severe to cause hypoventilation and hypoxemia. Phenylephrine, an α-adrenoceptor, can be used to decrease nasal vascular engorgement after anesthesia to prevent upper airway obstruction in these horses.22

Nasopharynx

The nasopharynx participates in swallowing as well as breathing, and it must be able to constrict to propel a bolus of food into the esophagus, and to dilate during exercise to allow unimpeded airflow to and from the lung. These functions are achieved by muscles that are uniquely positioned so that, as a group, they can both constrict and dilate the pharynx.23–25 In the horse, the exact functions of these muscles are incompletely understood, but from studies in horses and in other species, a general picture is emerging.

The hyoid apparatus is a very important structure that supports the pharynx as well as the root of the tongue and the larynx. The muscles of the hyoid apparatus dilate the pharynx by contracting on inhalation in the following manner. The geniohyoid and genioglossus muscles pull rostrally and ventrally, whereas the sternohyoid and sternothyroid muscles pull in a caudal ventral direction. The net effect is extension of the stylohyoid-ceratohyoid articulation, a ventral movement of the hyoid bone, and nasopharyngeal stabilization or even dilation (Fig. 40-4). One of the recommended surgeries for dorsal displacement of the soft palate is sectioning of the sternohyoid and sternothyroid muscles.26,27 The objective of this surgery is to move the epiglottis cranially, thereby better engaging the soft palate. From the aforementioned discussion, it is clear that sectioning of the sternohyoid and sternothyroid muscles prevents pharyngeal dilation and may encourage pharyngeal collapse. Indeed, measurements in exercising horses have indicated that sternohyoid and sternothyroid muscle sectioning slightly increases upper airway resistance in exercising horses.28

In racehorses, the tongue is often pulled forward and tied down to the mandible to prevent dorsal displacement of the soft palate. The tongue is attached to the hyoid bone via the genioglossus and hyoglossus muscles. Therefore, it is possible that the tongue-tie could dilate the pharynx. However, recent upper airway flow mechanics and computed tomographic studies have indicated that, in normal horses, the tongue-tie does not pull the hyoid apparatus forward and does not dilate the pharynx.29,30

The dorsal pharyngeal wall is supported by the stylopharyngeus muscles. These muscles insert on the dorsal nasopharyngeal wall, perpendicular to it, so that contraction of the stylopharyngeus muscles raises the wall of the dorsal nasopharynx, expanding, supporting, and preventing its collapse as pressures within the airway become more negative during inspiration (Fig. 40-5). Blockade of the ninth cranial nerves, which innervate these muscles, results in dorsal pharyngeal collapse and inspiratory airway obstruction during exercise.31

The upper airway is richly endowed with receptors that, when stimulated, activate upper airway dilator muscles, thereby stiffening the upper airway. For example, when the laryngeal mucosa is anesthetized, exercising horses have nasopharyngeal collapse and upper airway obstruction.32 During nasal occlusion, these horses can also experience dorsal displacement of the soft palate. This demonstrates that, in exercising horses, sensory and motor functions must be fully coordinated to maintain upper airway patency. The message to the surgeon is that the upper airway is a finely tuned instrument that can be easily disturbed by disease or surgical intervention.

The Soft Palate

The soft palate is another upper airway structure with multiple functions. It separates the nasopharynx from the oral pharynx and forms a tight seal around the larynx during breathing. However, during swallowing, the soft palate is elevated and closes the posterior nares, protecting the nasal passages from food and water. The position of the soft palate is determined by four muscles: the tensor veli palatini, levator veli palatini, palatinus, and palatopharyngeus muscles.33 Dysfunction of the tensor veli palatini destabilizes the cranial portion of the soft palate closest to the hard palate. In affected horses, the cranial portion of the soft palate bulges into the nasopharynx on inhalation.34 The pharyngeal branch of the vagus nerve innervates all of the muscles controlling the soft palate, except for the tensor veli palatini. Blockade of this nerve with a local anesthetic agent results in dorsal displacement of the soft palate.35 This demonstrates that coordinated activity of these muscles is necessary to stabilize the soft palate during breathing. The pharyngeal branch of the vagus nerve courses through the guttural pouch and lies in close proximity to the retropharyngeal lymph nodes. It is thought that, in clinical cases, dorsal displacement of the soft palate is the result of injury to this...
nerve because of retropharyngeal lymph node or guttural pouch inflammation.

Most upper airway conditions cause inspiratory airway obstruction, and expiratory airflow is unaffected. Dorsal displacement of the soft palate is an exception to this rule, since it is an expiratory obstruction. During exhalation, the paralyzed soft palate billows dorsally into the nasopharynx, markedly obstructing airflow and causing airway obstruction35 (Fig. 40-6).

The Larynx

The larynx functions as a very important guard, preventing food and water from entering the trachea. During swallowing, the arytenoid cartilages adduct completely, and the epiglottis pivots around its base so that the tip of the epiglottis moves dorsally and caudally. These maneuvers close the rima glottidis and prevent aspiration. Of course, during exercise the larynx must be opened maximally to allow unimpeded airflow. The larynx is one of the narrowest portions of the upper airway, and consequently lesions in this region cause significant airway obstruction. A good example of this is recurrent laryngeal neuropathy, also known as idiopathic laryngeal hemiplegia. In this condition, dysfunction of the left recurrent laryngeal nerve prevents appropriate contraction of the cricoarytenoideus dorsalis muscle, which fails to abduct the arytenoid cartilage during inhalation.36,37 In resting horses, pressure changes are insufficient to move the affected arytenoid cartilage and vocal fold into the airway lumen. On exhalation, positive pressures in the upper airway move the affected arytenoid cartilage abaxially, increasing airway caliber. However, on inhalation during exercise, luminal pressures are sufficiently negative to move the affected arytenoid cartilage and associated vocal fold into the airway, causing significant obstruction. The objective of surgical intervention in horses with recurrent laryngeal neuropathy is to prevent dynamic collapse of the affected arytenoid cartilage. For example, in these cases, prosthetic laryngoplasty is effective because the procedure stabilizes the affected arytenoid cartilage, preventing dynamic collapse. An example of a surgical procedure that is ineffective because it fails to adhere to this principle is subtotal arytenoidectomy.38 In this procedure, only the body of the arytenoid cartilage is removed, while the muscular process and the corniculate cartilage are left in place to help prevent postsurgical aspiration. However, during exercise the unsupported cartilage moves axially and obstructs the rima glottidis.38

As mentioned earlier, during swallowing the epiglottis pivots around its base, protecting the trachea. However,
During breathing and especially during exercise, the epiglotis must be stabilized. This is the function of the hyoepiglotticus muscle, which originates on the basihyoid bone and inserts on the base of the epiglottis. When the hyoepiglotticus muscle contracts, the epiglottis is pulled ventrally toward the base of the tongue, stabilizing the epiglottis. The hyoepiglotticus muscle is innervated by the hypoglossal nerves, and bilateral blockade of this nerve results in epiglottic retroversion during inhalation in exercising horses. Clinical cases of epiglottic retroversion have been described and probably are the result of disease interfering with neuromuscular control of upper airway dilator muscles, specifically the hyoepiglotticus muscle.

MEASUREMENT OF UPPER AIRWAY FUNCTION

Thus it is clear that the upper airway has often-competing functions, that small perturbations in function may cause significant airway obstruction, and that, for the surgeon, tolerance for error is small. Quantitative measurements of upper airway function help determine the effect of a particular condition on upper airway flow mechanics and the efficacy of surgical treatment. The best way to ensure that a surgical procedure is efficacious is to use quantitative methods of evaluation. The simplest method of evaluating upper airway flow mechanics is to measure the pressure needed to move air through the upper airway while the horse is undergoing a standard exercise test. Airway pressures may be measured using a multiple-hole catheter inserted into the trachea via the nostrils percutaneously. When airway pressures and airflow rates are measured simultaneously, upper airway impedance can be calculated as the ratio of pressure and flow. Measurement of impedance provides a more direct evaluation of changes in airway caliber than pressure measurements alone. Pressure and flow measurements have been used to determine the efficacy of many surgical procedures used in the treatment of upper airway conditions, such as recurrent laryngeal neuropathy and dorsal displacement of the soft palate.

Quantitative information may also be gained from analysis of airflow rates during the respiratory cycle. Flow-volume loop analysis is a test in which airflow rate is measured simultaneously with the tidal volume. Figure 40-7 shows a tidal breathing flow-volume loop from a horse exercising at maximal heart rate before (baseline) and after induction of laryngeal hemiplegia (LRLN). Note that expiration is unaffected, but there is severe inspiratory flow limitation with LRLN throughout the inspiratory portion of the tidal volume.

PHYSICAL EXAMINATION

Although a large portion of the upper respiratory tract is not easily seen or palpated, a thorough physical examination can provide critical details that assist in its overall assessment. A physical examination is an essential part of any evaluation. It not only provides information on present pathology but also reveals clues about previous surgical procedures. Before beginning the examination, a complete history should be obtained. Specific questions should be asked about respiratory noise, dysphagia, exercise intolerance, coughing, nasal discharge, and any previous treatments or surgery. All of this information should be interpreted in conjunction with the physical examination findings and the results of the other diagnostic procedures to establish a diagnosis.

The physical examination begins with visual assessment of any asymmetry of the head and nares, and inspection for...
PHYSICAL EXAMINATION

Although a large portion of the upper respiratory tract is not easily seen or palpated, a thorough physical examination can provide critical details that assist in its overall assessment. A physical examination is an essential part of any evaluation. It not only provides information on present pathology but also reveals clues about previous surgical procedures. Before beginning the examination, a complete history should be obtained. Specific questions should be asked about respiratory noise, dysphagia, exercise intolerance, coughing, nasal discharge, and any previous treatments or surgery. All of this information should be interpreted in conjunction with the physical examination findings and the results of the other diagnostic procedures to establish a diagnosis.

The physical examination begins with visual assessment of any asymmetry of the head and nares, and inspection for the presence of any asymmetry of the head and nares, and inspection for any asymmetry of the head and nares, and inspection for
the presence of any nasal or ocular discharge. Facial deformity in front of the eye is consistent with either primary or secondary sinus disease. There may be associated nasal discharge via the nasomaxillary opening, or ocular discharge from occlusion of the nasolacrimal duct. Furthermore, chronic sinus disease may result in nasal passage obstruction. Placing a hand in front of each nostril provides a crude indication of airflow from each nostril. Subtle changes are very difficult to detect, but an obstructive lesion in one nasal passage may result in significant asymmetric airflow. Percussion of a normal sinus should result in a hollow sound. The presence of an abnormal structure in the sinus can change the character and intensity of the sound, but this depends on many factors and can often be misinterpreted.

Nostril disease is uncommon, but palpation of each nostril and the alar folds in the dorsal aspect of the nares can often determine if a problem is present. If alar fold redundancy and obstruction during exercise is suspected, the alar folds can be tied with umbilical tape over the bridge of the nostril during an exercise period. Mitigation of noise confirms the diagnosis.

Palpation of the larynx can be a difficult skill to develop, but once mastered it is very helpful in assessing laryngeal function. An assistant should hold the horse’s head slightly elevated. The clinician can stabilize the right side of the larynx with one hand and palpate the left side of the larynx with the other hand. By alternating hands, both sides of the larynx can be compared. The muscular processes of the larynx are in a fairly dorsal position and are slightly smaller than a person’s knuckle. The caudal border is attached to the cricoarytenoideus dorsalis muscle, and when the muscle is atrophied, the muscular process feels more prominent than on the other side. Mild asymmetry is a common finding in horses with normal laryngeal function, but more overt asymmetry is usually consistent with the horse’s inability to maintain abduction of the affected arytenoid cartilage. If the left muscular process cannot be easily palpated, it may be covered by scar tissue from a previous laryngoplasty, or the arytenoid cartilage may be chondritic. A scar from laryngoplasty is not easily palpated at the level of the skin or the arytenoid cartilage may be chondritic. A scar from previous surgery was performed. Clipping the hair ventral to the larynx often leaves a palpable scar. The skin should be examined for any sign of a defect secondary to a myectomy, and the tracheal rings should be palpated for any abnormalities associated with trauma or previous surgery.

**DIAGNOSTIC IMAGING**

**Videoendoscopic Examination at Rest**

The endoscopic examination of the upper airway is still the primary diagnostic tool. Most diagnoses can be obtained from a complete resting endoscopic examination. Videoendoscopic equipment, commercially available for over 20 years, provides the best method for viewing the upper airway. Several companies produce videoendoscopes with similar specifications, and user preference and cost often determine which system is purchased. The main components of a videoendoscopy system consist of the videoscope itself, the video processor, the light source, and the video monitor. A videoscope with an outer diameter of less than 9.5 mm can be used easily on all adult horses and on most foals. Smaller videoendoscopes with an outer diameter of less than 8.5 mm are also available for younger foals, but the tradeoff is a smaller biopsy channel (2.2 mm versus 2.8 mm). Most videoendoscopes have a field of view of 120 degrees, and tip deflection angles of 210 to 90 degrees. The working length for most videoendoscopes is approximately 103 cm, which is ample for upper respiratory work. Light sources are fairly standard xenon lamps with illumination of 300 watts. Fiberoptic endoscopes typically have only half the illumination of the videoscopes, and a much smaller field of view, which significantly limits the clinician’s ability to clearly view all abnormalities.

Image storage is crucial for documentation and re-evaluations. It is therefore beneficial to have a recording unit or a printer with any videoendoscopic system. Any VHS tape deck can be used as a recording unit. More recently, advancements have been made that allow digital images to be downloaded directly to a laptop computer or a compact disk.

The clinician should have a plan of how and what to evaluate during the examination. The patient should not be sedated and should be restrained only with a twitch to ensure no interference with any assessments of airway function. It is easiest to have an assistant pass the endoscope down the ventral meatus of one nostril until the tip of the endoscope enters the pharynx. The pharynx and larynx should be evaluated first, and then the nasal passage can be evaluated while backing the endoscope out of the horse’s nose. If there is a suspected abnormality in the nasal passage, the normal side should be evaluated first to minimize any trauma to or resentment from the horse before evaluating the abnormal side.

The amount of lymphoid hyperplasia in the pharynx is variable and depends on the horse’s age. It is common for the younger horse to have lymphoid hyperplasia, but it has not been correlated with any specific dysfunctions. The epiglottis should always be positioned dorsal to the palate and should have a distinct serrated edge with a clear vascular pattern on the dorsal surface. The corniculate processes of the arytenoid cartilages should be evaluated for their overall appearance, relative position, and degree of movement. Thickening, ulcerations, or granulation tissue are probably indicative of chondrosis (Fig. 41-1). Inability to fully abduct relative to the other side is indicative of recurrent laryngeal neuropathy. (Recurrent laryngeal neuropathy is the term used to depict the naturally occurring form of laryngeal...
experience dynamic collapse of that arytenoid during high-speed exercise. It may appear to make sense to evaluate the horse’s throat from both nares to get a more accurate assessment of arytenoid abduction, but the authors do not think it makes a significant difference.

Inability to fully adduct an arytenoid cartilage may be a result of previous laryngoplasty, and palpation of the larynx and assessing the skin for a surgical scar should help determine the diagnosis. The slap test can be used to induce adduction of the arytenoid cartilages, but this is not a valuable test to fully evaluate laryngeal function. The vocal cords and saccules should also be examined for any evidence of previous surgery. Incomplete ablation with the laser may yield scarring and deformation of the vocal cords, or a cord may be absent (Fig. 41-2).

The endoscope should be passed into the trachea to determine the presence of any discharge or feed material, indicative of aspiration. When the endoscope exits the trachea, it is common for the horse to displace its soft palate, but a normal horse should replace it quickly. If the horse does not replace its palate quickly, it can be stimulated to swallow by infusing water into the pharynx or by quickly bumping the pharyngeal wall with the endoscope. If the horse still does not replace the palate below the epiglottis, this may indicate some structural abnormality under the epiglottis, or some pharyngeal dysfunction that may be best observed during high-speed exercise. If a subepiglottic abnormality is suspected, other imaging techniques may be indicated, but the clinician can also spray the epiglottic region with topical anesthetic through the biopsy channel of the videendoscope, followed by manipulation of the epiglottis with a long bronchoesophageal forceps through the nose to look underneath.

Once the examination of the pharynx and larynx is complete, the remainder of the upper respiratory tract should be examined. The guttural pouch openings should be clear of any discharge. The presence of discharge at the opening of the guttural pouch may be an incidental finding caused by discharge originating from another location and becoming lodged at the opening. Despite this, further endoscopic evaluation of the guttural pouches is always warranted. This is most often done at the end of the examination, and it may require a small dose of intravenous sedation. Temporohyoid disease can often be seen as an enlargement of the stylohyoid bone at the most dorsal aspect of the guttural pouch (Fig. 41-3). The ethmoid recess, turbinates, septum, and region of the nasomaxillary openings (caudal middle meatus) should all be evaluated as the endoscope is slowly withdrawn from the nostril. Discharge running down the ventral turbinate, with material exiting the nasomaxillary opening, is often a sign of sinus disease. Both nasal passages should be evaluated if there is any suspicion of a sinus or nasal passage problem. It is often difficult to discern small deviations in the nasal passage because the endoscopic view provides a very magnified but small field of view. Radiographs are a helpful complementary procedure if septal deviation or some type of sinus disease is suspected.

### Videoendoscopic Examination during Exercise

Although a great deal of information can be gained from endoscopy in the resting horse, there are many occasions when a functional abnormality is suspected but no abnor-

malities are detected during the resting endoscopic examination—for example, when there is exercise intolerance or abnormal respiratory noise during exercise. Conditions that can lead to this scenario include forms of pharyngeal collapse, axial deviation of the aryepiglottic folds, epiglottic retroversion, intermittent epiglottic entrapment, and dorsal displacement of the soft palate. Endoscopic examination immediately after exercise may be valuable in some cases, but it can be misleading. Even normal horses have a much more flaccid-looking upper airway that displaces more easily when first pulling up after exercise. Like all skeletal muscles, the muscles that maintain structural integrity of the upper airway relax at the conclusion of strenuous exercise. Therefore, any conclusion based on an endoscopic examination after exercise, particularly with respect to the functional stability of the pharynx, may be inaccurate.

Treadmill endoscopy may seem to be the easiest and most reliable way to make a diagnosis, but this examination must also be evaluated critically. Accurate conclusions from an endoscopic examination on a high-speed treadmill cannot be drawn from an endoscopy while a horse is running, without specifying the exertional effort. The exercising conditions must simulate the horse’s normal working conditions as closely as possible. In the lower respiratory tract, the effects of running a longer distance at a slower speed are not equivalent to the effects of running a shorter distance at a faster speed. This may also be the case in the upper respiratory tract. Furthermore, some of the upper respiratory problems are not only dynamic but also intermittent, and if all the same conditions (e.g., speed, head/neck flexion, fatigue) are not reproduced, a false-negative outcome is likely to be obtained (Fig. 41-4). A Holter monitor can be employed to record the horse’s heart rate during exercise, and if it is approximately 220 beats per minute or greater, the record will provide evidence that the horse is exercising at or near its maximal heart rate. Of the known upper respiratory abnormalities, dorsal displacement of the soft palate is the most likely not to be reproduced on a high-speed treadmill examination despite circumstantial evidence of the condition under field conditions.

Horses that can be examined by treadmill endoscopy must be as fit as they are for competition. A horse out of work may be too unfit to withstand a maximal exertional effort on the treadmill, and the problem to be diagnosed may not manifest itself. All horses must first be acclimatized to the treadmill before attempting an actual test. This can usually be accomplished with 1 to 2 hours of schooling, taking the horses through the different gaits, and making
sure they can obtain adequate speed. During the schooling and testing periods, protective boots and leg wraps are recommended. Hobbles and harness are always recommended for pacing Standardbreds and are introduced in the schooling period. The horse must be in condition and should be prepared for the examination as if it were the date of a competition or race.

The treadmill must be capable of obtaining a speed of at least 14 m/s with relatively rapid acceleration and deceleration potential for any racehorse examinations. Padded rails with polycarbonate sides, or an equivalent material, should be present to maintain the animal’s position on the belt and protect individuals on either side of the treadmill. Large overhead fans in a temperature-controlled environment are also required. Sweat evaporation is the horse’s primary form of body temperature regulation. Under racing conditions, the animal creates its own breeze to enhance evaporation; however, on the treadmill, the horse is stationary, and fans are required to prevent overheating. Two people, holding ropes that are attached to both sides of the horse’s halter, keep the horse centered on the treadmill. An individual behind the horse encourages the horse forward, and another person closely monitors the horse’s gait and controls the treadmill speed, ensuring the horse’s position on the treadmill. One final person is needed to guide the endoscope during the examination (Fig. 41-5). For safety reasons, and to ensure a valid test, it is extremely important that the team of individuals carrying out the examination be experienced. The specific protocol used depends on the type of competition the horse is normally engaged in, and it should mimic these circumstances as closely as possible. Generally, after an initial warm-up period, the treadmill is stopped, the endoscope is passed via the right nostril into the pharynx, and its position is maintained by Velcro straps connecting the shaft of the endoscope and the noseband of the horse’s halter (Fig. 41-6). A typical exercise protocol for the Thoroughbred racehorse is as follows:

1. Warm up through a combination of walk/trot/canter for 2000 m.
2. Walk again until heart rate is 80 to 90 beats per minute, stop, and pass endoscope.
3. Accelerate to 9 m/s (incline treadmill to 3 degrees for Thoroughbreds).
4. Accelerate to 11 m/s for 400 meters.
5. Accelerate to 12 m/s for 400 meters.
6. Accelerate to 14 m/s for 1600 meters.
7. Decelerate to 12 m/s for 400 meters.

Most horses suffering from a poor performance problem are unable to meet the demands of this protocol. Such
horses should be exercised at their own maximal exertional effort. Determination of maximal effort is a subjective assessment by the clinician in conjunction with heart rate evaluation. Recording the entire endoscopic examination, and reviewing it on slow-motion playback, is sometimes necessary, because most abnormalities occur rapidly within the respiratory cycle. Occasionally, stimulating a swallow with water through the endoscope, or altering the speed of the treadmill during the test, will induce the dynamic respiratory problem.

**Radiography**

Although treadmill endoscopy is invaluable for evaluating the dynamics of the upper respiratory tract during exercise, other imaging techniques, such as radiography and computed tomography, are just as essential in fully evaluating the upper respiratory tract. Radiography and computed tomography are particularly valuable in the assessment of structural abnormalities in areas that are difficult to explore with the endoscope.

The larynx, pharynx, and guttural pouches can be clearly imaged with standard radiographic techniques. Computed radiography and digital radiography provide greater detail and ability to manipulate images. To acquire a lateral image of the laryngeal structures, the x-ray beam should be centered just rostral and dorsal to the angle of the mandible. A dorsoventral projection is usually not of benefit in evaluating these structures.

Air throughout the upper respiratory tract provides good contrast for structures within the pharynx and larynx. Any masses or swelling external to the lumen will lead to obvious compression of the pharyngeal vault. The epiglottis should appear as a thin structure on top of the soft palate. Subepiglottic or palatal lesions may cause dorsal displacement of the soft palate (Fig. 41-7), but heavy sedation of the horse may also precipitate displacement of the palate, and this finding should not be over-interpreted. Measurements have been made of epiglottic length on lateral radiographs and correlated with dynamic upper respiratory dysfunction. Clinicians depend more often on their endoscopic assessment of epiglottic length and apparent stiffness than on radiography. The arytenoids and the remainder of the laryngeal cartilages can be seen dorsal and caudal to the epiglottis. Mineralization of these structures may be associated with normal aging or with an inflammatory process such as arytenoid chondritis. Infrequently, abnormal air density may be seen around the larynx and could be consistent with severe laryngeal infection. The sacculles should be seen as small air densities between the epiglottis and corniculate processes.

The guttural pouches are thin-walled, air-filled cavities that extend from the pharynx and project dorsal to the larynx. The guttural pouches are outpouchings of the eustachian tubes, and normally the stylohyoid bone is seen traversing through the guttural pouch. Enlarged retropharyngeal lymph nodes may lead to compression of the guttural pouch ventrally. Fluid associated with guttural pouch empyema or hemorrhage can typically be seen as increased soft tissue density or a fluid line. Temporohyoid disease may be seen as enlargement of the stylohyoid bone, but this condition is more reliably detected during the endoscopic examination.

Radiography can be very beneficial in imaging most abnormalities within the sinus, but the technique does have limitations. Dorsoventral, lateral, and oblique projections are the minimum of radiographic views that should be taken to fully evaluate the sinuses. Although air density provides good contrast, superimposition of structures can make interpretation difficult, and familiarity with normal sinus architecture is essential. A fluid line can be seen in the lateral projection in many cases of sinusitis, but if the entire sinus is full, only increased soft tissue density will be seen (Fig. 41-8). Often the borders of the frontal and maxillary sinuses can be discerned easily. The septum between the caudal and rostral maxillary sinuses can be best appreciated on a lateral radiograph, but sinusitis or neoplasia may result in significant distortion of normal anatomy. Contrast sinusography can be used to better help delineate abnormalities. Contrast material can be injected through standard portals for sinus centesis, and filling defects will define the extent of lesions.

Sinusitis can be primary, or secondary to another problem such as tooth infection or neoplasia. It can be difficult to make this distinction with standard radiography, but this determination is essential in developing an appropriate treatment plan. If bony lysis is present on standard radiographs, the sinusitis is most likely secondary to some other, primary problem, but the absence of lysis is not definitive for a primary sinusits. Sinuscopy can be used to visualize the internal aspects of the sinus, but it has limited application. More sensitive imaging techniques are often of greater benefit.

**Scintigraphy**

Scintigraphy is an extremely sensitive technique for bony remodeling. It can be used to evaluate the equine head reliably for the presence of dental disease, and it can be used to distinguish between dental disease, neoplasia, and
primary sinusitis. Bone phase images are acquired 3 to 4 hours after an intravenous injection of a radioisotope. The images are obtained by a gamma camera, and regions of interest are analyzed. Although scintigraphy can be used to determine the presence of dental disease, it may be difficult to discern the specific tooth that is involved with great certainty. Scintigraphy has a significant advantage over other imaging techniques because general anesthesia is not required. The images are acquired with the standing sedated animal, and multiple views can be taken to help minimize superimposition of structures. Many hospitals now have scintigraphic capability.

Computed Tomography and Magnetic Resonance
Computed tomography (CT) has a distinct advantage over scintigraphy and standard radiography because highly detailed cross-sectional images can be obtained. CT can discriminate tissues with only a 0.5% difference in density, whereas a 10% change in density is necessary to detect a radiographic difference. The images are obtained using x-rays, but the x-ray tube and detectors encircle the patient, acquiring images from many angles. The resulting images are cross-sectional slices of a specified thickness (Fig. 41-9). This eliminates the problem of superimposition encountered with conventional radiography, and it allows precise determination of an abnormality. By knowing in greater detail the extent of a lesion, a more precise surgical plan can be made. Unfortunately, this imaging modality is available only at certain larger hospitals and requires general anesthesia and specially adapted equipment to accommodate large animals.
Magnetic resonance (MR) imaging is another diagnostic modality that can be used to diagnose upper respiratory disease, but it is not as readily available as the other techniques. Furthermore, MR also requires general anesthesia to acquire images of the head. It is generally thought to be a superior imaging technique for soft tissue, but MR can be just as good at discerning bony abnormalities. The normal cross-sectional anatomy of the equine head has been described. A distinct advantage of MR over CT is that MR imaging can be multiplanar without image quality loss. CT slices are always oriented perpendicular to the long axis of the table and body region in the gantry. The CT images can be reconstructed with computer software to provide images in other planes, but there is a significant loss of image quality.

**SOUND ANALYSIS**

Horses with upper airway conditions often have exercise intolerance and make a respiratory noise. Although reduced performance may be caused by dysfunction of many body systems, respiratory noise during exercise is a specific indication of upper airway disease. Furthermore, in sport horses, the respiratory noise associated with an upper airway condition is often more worrisome to the owner than reduced performance.

One cannot hear respiratory noises in exercising horses very well. Even the jockey, driver, or rider, who is nearest to the source of the noise most of the time, does not hear respiratory sounds well because the noise is obscured by other sounds associated with exercise such as wind noise and footfall. A listener standing near the track gets "a snapshot" of the noise at best. Also, respiratory sounds do not always occur throughout the exercise period. In some instances, the sounds are more obvious at maximum exercise, but in other cases the sounds are intermittent, or occur as the horse is finishing the exercise. For these reasons, recording of respiratory sounds in exercising horses is advantageous, and it also permits analysis after the recording. Recording of respiratory sounds in exercising horses is simple and inexpensive and requires minimal equipment.

The sounds can be recorded throughout the exercise period, in the field, and under conditions in which the horse normally works. This gives the veterinarian complete and verifiable information about the respiratory noise.

Evaluation of respiratory sound during exercise is also useful in the assessment of effectiveness of surgical procedures used in the treatment of upper airway conditions. In many horses with upper airway conditions, the primary objective of surgery is to reduce the respiratory noise. In these cases, evaluation of sound production before and after surgery is a good way to determine surgical success.

**Methodology**

Although several methods are described in the literature, the authors record respiratory sounds in exercising horses in the following manner. A unidirectional microphone with a cardioid pickup pattern is attached via a flexible wand to a cavison (Fig. 41-10). This type of microphone centers the sound pickup toward the front of the microphone and helps reduce extraneous sounds such as footfall and track noise that originate behind and to the side of the microphone. The microphone is covered with a windsreen, and it is placed equidistant between the horse's nostrils, approximately 4 cm from the horse's nose. In this way, the microphone is as close to the source of sound to be recorded as possible without being placed in the respiratory air stream. The microphone is attached to an audio recorder with a compression circuit. This kind of recorder automatically adjusts the gain, decreasing the recording of extraneous noises. The advantages of this technique are that it is easily used in the field, and it records respiratory sounds that are also heard by human observers.

Just listening to the audiotape of respiratory sounds made by exercising horses is revealing. The listener can appreciate factors such as respiratory rate and consistency, the number of swallows, the frequency of stride lead changes, and whether abnormal respiratory sounds are present.

Sound can be characterized in terms of time, frequency, and intensity. A sound analysis technique that evaluates these characteristics concurrently is spectrogram analysis. A spectrogram is a three-dimensional plot of frequency on the vertical axis, time along the horizontal axis, and sound intensity in the third dimension. Sound intensity is often plotted in terms of color, or relative darkness. This powerful technique has been used commonly to study human voice or biologic sounds such as bird songs, and also to evaluate upper respiratory sounds made by exercising horses. Spectrogram analysis requires a personal computer and commercially available software. Listening to the audiotape and viewing the spectrogram at the same time is an effective method of sound evaluation.

**Upper Airway Sounds in Exercising Horses**

In normal exercising horses, most sounds are heard during exhalation and are present throughout this portion of the respiratory cycle. Inspiratory sounds are less than half as loud as sounds made during exhalation. Sound level increases as speed increases. Almost all of the sound intensity occurs at frequencies below 4 kHz, with...
most of the sound intensity concentrated at frequencies below 800 Hz. Recurrent laryngeal neuropathy (RLN) and experimentally induced laryngeal hemiplegia (LH) are characterized by a loud inspiratory noise. This noise contains higher frequencies than normal expiratory sounds and has three bands in the frequency domain called formants. These formants are centered at approximately 300, 1700, and 3700 Hz (Fig. 41-12). Human hearing is most acute between 2000 and 4000 Hz. The sound formant centered at about 1700 Hz has significant sound intensity and is in the range of acute human hearing, so this is the one that contributes most to the perception of the high-frequency whistle or roar associated with RLN. The highest-frequency formant has the least sound intensity, and it is not present in all RLN-affected horses. The sound intensity of the formant centered at about 300 Hz is in a region where human hearing is less acute, so this lower-frequency noise does not appear prominent to the human ear. Whether the spectral pattern just described is unique for RLN remains to be determined. If this is the case, spectrum analysis of upper airway sounds in exercising horses could be used as a definitive diagnostic tool for RLN.

Dorsal displacement of the soft palate occurs intermittently during exercise; therefore, the abnormal noise associated with this condition is also intermittent. Often, the soft palate displaces near the end of the exercise, or as the horse pulls up. In some horses, the abnormal sound can be heard throughout the exercise period. In affected horses, expiratory sounds are abnormal. The noise is characterized by rattling, which is seen on the spectrogram in the time

![Figure 41-11. Spectrogram of respiratory sounds in a normal galloping horse. Timing is on the abscissa, frequency on the ordinate. The gray scale indicates sound intensity. Inspiration is indicated by a star, expiration by an arrow.](image)

![Figure 41-12. Spectrogram of respiratory sounds in a galloping horse with experimentally induced laryngeal hemiplegia. Notice the inspiratory bands of sound (formants) centered at approximately 0.3, 1.7, and 3.7 kHz ($F_3$, $F_2$, and $F_1$, respectively).](image)
domain as bars of sound with a periodicity of about 32 ms (Fig. 41-13). Most of the sound energy is below 4000 Hz, but the range is up to approximately 10,000 Hz.[30] In some horses with dorsal displacement of the soft palate, respiratory sounds are normal, but in others, an inspiratory noise similar to the noise described for exhalation is also heard. In these cases, the inspiratory noise is often less loud than the expiratory noise. During exercise, affected horses often swallow frequently, presumably in an attempt to keep the soft palate in its normal position.

It is likely that vibrations of the dorsally displaced soft palate are the source of the upper airway noise. The rate and amplitude of soft palate vibration are a function of the airflow velocity, the compliance of the dorsally displaced soft palate, and the geometry of the individual horse's upper airway. Combined, these factors explain why some horses with dorsal displacement of the soft palate make no noise, whereas in others the noise is also apparent during inhalation. Listening to the recorded respiratory sounds made by a horse with dorsal displacement of the soft palate while concurrently viewing the spectrogram is an effective way to diagnose the condition.

RLN and dorsal displacement of the soft palate can be experimentally reproduced and are the most common upper airway conditions of horses.[31,32] Consequently, noises associated with these conditions have been studied best. However, upper airway conditions such as pharyngeal collapse, epiglottic entrapment, aryepiglottic fold collapse, and rostral soft palate collapse are also associated with respiratory noise during exercise. Although the associations between specific conditions and their corresponding spectrogram patterns must still be made, in the future it is likely that each upper airway condition associated with noise production will have a well-described "voiceprint," allowing a presumptive spectrogram-based diagnosis of the condition in the field.

**Surgical Treatment for Recurrent Laryngeal Neuropathy**

Surgical procedures used to treat RLN include prosthetic laryngoplasty, various combinations of laryngeal ventricle and vocal cord excision, often combined with laryngoplasty, and nerve–muscle pedicle grafting.[33-38] The effect of these surgical procedures on upper airway function has been well studied.[31,33,36-40] Fewer studies have investigated the ability of these procedures to reduce respiratory noise.[22,30] In one study, bilateral ventriculocordectomy effectively reduced respiratory noise in horses with experimentally induced laryngeal hemiplegia.[22] Respiratory noises associated with the condition were almost completely eliminated, although spectrum analysis revealed some residual abnormal respiratory sounds (Fig. 41-14). Noise reduction required up to 90 days after the surgery.

The most commonly used surgical technique to treat RLN is prosthetic laryngoplasty.[34-36] The procedure significantly improves upper airway flow mechanics in RLN-affected horses, and many horses have raced successfully after surgery.[35,36] Prosthetic laryngoplasty reduces upper airway noise in horses with laryngeal hemiplegia, but it is not as effective as bilateral ventriculocordectomy in this regard (see Fig. 41-14). Additionally, respiratory noise reduction occurs more rapidly than with bilateral ventriculocordectomy. Residual respiratory noise after surgery is often used to determine the surgical success of prosthetic laryngoplasty.[34] This method of evaluation assumes a tight correlation between respiratory noise and airway obstruction. In fact, in horses with experimentally induced LH, the correlation between residual airway obstruction after prosthetic laryngoplasty and residual noise is weak.[41] Therefore, the residual noise during exercise cannot be used as a predictor of improvement in upper airway function in individual horses after laryngoplasty.

---

**Figure 41-13.** Spectrogram of respiratory sounds in a galloping horse with experimentally induced dorsal displacement of the soft palate. Note the “rattling” of the expiratory sound (arrows).
Endoscopically guided laser surgery has been used to perform vocal cordectomy in RLN-affected horses. In a recent study, the authors evaluated unilateral laser cordectomy and concluded that the procedure does not effectively reduce upper airway noise in horses with experimentally induced laryngeal hemiplegia (see Fig. 41-14). Unilateral laser cordectomy results in removal of the left vocal cord but not of the entire laryngeal ventricle. This study suggests therefore that the laryngeal ventricle rather than the vocal cord may be the primary source of LH-associated noise.

In summary, respiratory sound recording in exercising horses is easy and inexpensive and can be accomplished under field conditions. The sound can be analyzed by simply listening to the recording, and by spectrogram analysis. Just listening to the recording gives the veterinarian insight into breathing patterns and abnormal noises during exercise. Spectrogram analysis provides a voiceprint that in many cases suggests the presence of a specific upper airway condition. Respiratory sound analysis can also be helpful in evaluating surgical procedures aimed at reducing respiratory noise in horses with upper airway disease.

Note that respiratory noise reduction is most effective after VC, and least effective after LC.
the level of 111/211 (3rd molar) to the level of 106/206 (2nd premolar in the upper arcade). The ventral part of the naris leads directly into the nasal cavity from the lateral mass of the ethmoid bone.

The horse's extensive paranasal sinus system consists of six pairs of sinuses: the dorsal (endoturbinate I), middle (endoturbinate II), and ventral nasal conchal sinuses; the sphenopalatine sinus; the frontal sinus; and the maxillary sinus (Fig. 42-1). The major clinically significant sinuses are the frontal and maxillary sinuses. All the sinuses communicate with the nasal cavity directly (maxillary sinus) or indirectly (dorsal, middle, and ventral conchal sinuses; frontal sinus; and sphenopalatine sinuses) through the maxillary sinus. The paranasal sinuses are important clinically because they are susceptible to infections that extend from the nasal cavity or from the alveoli of the caudal upper cheek teeth (see Chapter 30).

Each conchal sinus is divided into a rostral and a caudal compartment by a septum. The caudal compartment of the dorsal concha forms the dorsal conchal sinus, which communicates with the frontal sinus, forming the conchofrontal sinus. The caudal compartment of the ventral concha forms the ventral conchal sinus, which communicates with the rostral maxillary sinus over the infraorbital canal through the conchomaxillary opening.

The maxillary sinus is the largest of the sinuses. It is divided into rostral and caudal compartments by an oblique septum. The root of the maxillary 1st molar tooth (109/209) (see Fig. 30-1) usually enters the rostral compartment, and the roots of the 2nd (110/210) and 3rd molars (111/211) usually enter the caudal compartment. The caudal maxillary sinus is partially divided by the infraorbital canal, over which it communicates with the sphenopalatine sinus. The reserve crowns of the maxillary teeth (see Chapter 30). Numerous small ethmoturbinates project into the caudal part of the nasal cavity from the lateral mass of the ethmoid bone.
Nasal Cavity

The nasal cavity is divided into equal halves by the nasal septum and the vomer bone. The reserve crowns of the upper cheek teeth (see Chapter 30) usually enter the rostral compartment, and the root of the maxillary 1st molar tooth (109/209) communicates dorsally with the conchofrontal sinus via the infraorbital canal through the ventral conchal sinus, which communicates with the sphenopalatine sinus. It is partially divided by the infraorbital canal, over which it communicates with the sphenopalatine sinus. The caudal compartment of the ventral concha forms the dorsal conchal sinus, which communicates with the frontal sinus, forming the conchofrontal sinus (Fig. 42-1). The major clinically significant sinuses are the frontal and maxillary sinuses. All the sinuses communicate with the nasal cavity directly (maxillary sinus) or indirectly (dorsal, middle, and ventral conchal sinuses; the sphenopalatine sinus; the frontal sinus; and the maxillary sinus (endoturbinate II), and ventral nasal conchal sinuses; the paranasal sinus system consists of six pairs of sinuses: the dorsal (endoturbinate I), middle (endoturbinate II), and ventral nasal conchal sinuses; the sphenopalatine sinus; the frontal sinus; and the maxillary sinus). The paranasal sinuses are important clinically because they are susceptible to infections that extend from the nasal cavity or from the alveoli of the caudal upper cheek teeth (see Chapter 30).

Conchal Sinuses

Each conchal sinus is divided into a rostral and a caudal compartment by a septum. The caudal compartment of the dorsal concha forms the dorsal conchal sinus, which communicates with the frontal sinus, forming the conchofrontal sinus. The caudal compartment of the ventral concha forms the ventral conchal sinus, which communicates with the rostral maxillary sinus over the infraorbital canal through the conchomaxillary opening. The maxillary sinus is the largest of the sinuses. It is divided into rostral and caudal compartments by an oblique septum. The root of the maxillary 1st molar tooth (109/209) usually enters the rostral compartment, and the roots of the 2nd (110/210) and 3rd molars (111/211) usually enter the caudal compartment. The caudal maxillary sinus is partially divided by the infraorbital canal, over which it communicates with the sphenopalatine sinus. It communicates dorsally with the conchofrontal sinus via the ethmoturbinate projects into the caudal part of the nasal cavity from the lateral mass of the ethmoid bone.

CHAPTER 42

Nasal Passages and Paranasal Sinuses

Frank A. Nickels

FUNCTIONAL ANATOMY

External Nares

The external nares or nostrils in the horse are the openings into the nasal passages; they are widely placed and have an unusual shape. The dorsal and lateral margins of the nares, the alae, are supported by the alar cartilages, which are attached to the rostral end of the nasal septum dorsally. The thick alar fold divides each naris into dorsal and ventral parts. The dorsal part leads into a blind sac called the nasal diverticulum, which occupies this area of the skull. Two major nasal conchae (thin scrolls of cartilage and bone) in each nasal cavity divide the nasal passage into the dorsal, middle, ventral, and common meatus. The dorsal concha extends from the cribriform plate of the ethmoid bone to the level of the 106/206 (2nd premolar in the upper arcade). The ventral concha extends from the level of the 111/211 (3rd molar) to the level of 106/206 (see Chapter 30). Numerous small sinuses communicate with the nasal cavity directly (maxillary sinus) or indirectly (dorsal, middle, and ventral conchal sinuses; the sphenopalatine sinus; the frontal sinus; and the maxillary sinus). The paranasal sinuses are important clinically because they are susceptible to infections that extend from the nasal cavity or from the alveoli of the caudal upper cheek teeth (see Chapter 30).
Frontomaxillary opening at the level of the osseous lacrimal canal and the medial wall of the orbit. It also communicates with the nasal cavity through a compressed nasomaxillary opening into the caudal aspect of the middle meatus. The rostral maxillary sinus is also divided by the infraorbital canal into medial and lateral compartments. The medial compartment of the rostral maxillary sinus communicates with the middle nasal meatus via a narrow slit, the nasomaxillary opening. The rostral compartment communicates with the ventral conchal sinus over the infraorbital canal through the conchomaxillary opening. The volume of the sinus continues to increase from birth through the life of the horse as the teeth continue to erupt and migrate forward. The maxillary sinus is more predisposed to disease than the other sinuses because of direct communication with the nasal cavity and its association with the dental alveoli.

**Frontal Sinus**

The frontal sinus occupies the dorsal part of the skull. It extends from a point midway between the infraorbital foramen and the medial canthus of the eye to a point midway between the caudal margins of the orbit in the mature horse. An extensive communication exists between the rostromedial aspect of the frontal sinus and the dorsal conchal sinus; together they are referred to as the conchofrontal sinus.

**Sphenoid and Palatine Sinuses**

The sphenoid and palatine sinuses are usually contiguous in the horse, forming the sphenopalatine sinus. The sphenoid and palatine sinus compartments communicate under the ethmoidal labyrinth. The sphenopalatine sinus communicates freely with the caudal maxillary sinus.

**DISEASES OF THE NARES**

Diseases of the nares are relatively rare. The most common clinical signs are reduced airflow, nasal stertor, and occasionally facial distortion. The condition of the nares can usually be determined by observation and palpation.

**Epidermal Inclusion Cysts (Atheromas)**

These cysts, located in the dorsolateral aspects of the nasal diverticulum, were once thought to be sebaceous cysts and were referred to as atheromas. A recent report describing the histologic appearance found no remnants of sebaceous glands or cells in the cyst wall;thus, a more accurate and descriptive name, epidermal inclusion cysts, has been proposed. These cysts are usually single, unilateral, spherical nodules that can vary from 3 to 5 cm in diameter. Epidermal inclusion cysts of the nasal diverticulum are easily identified by visual appearance and location. An accurate diagnosis can be confirmed by cytologic examination of a fine-needle aspirate. Epidermal inclusion cysts are rarely associated with impaired athletic performance and need not be removed unless indicated for cosmetic reasons.

Surgical extirpation can be performed on a standing horse with sedation and local infiltration anesthesia. The skin of the external nares is prepared for aseptic surgery, as is the nasal diverticulum because of the possibility of inadvertent penetration into the diverticulum. The skin and subcutaneous tissue are incised over the lesion, and the cyst is removed by dissection. Care is taken not to rupture the cyst wall. Closure of the incision is routine, and the aftercare is minimal. An alternative method of removal of epidermal inclusion cysts has been described. The cyst is lanced into the nasal diverticulum through a stab incision, and the cyst lining is everted using a roaring burr. The lining is transected using scissors, and the wound is left to heal by second intention. Recurrence has not been reported.

**Redundant Alar Folds**

The alar fold has been incriminated as a source of respiratory noise in the horse. To determine whether this is the source of abnormal noise or exercise intolerance, a large temporary mattress suture can be placed through the skin of
each alar fold and tied over the bridge of the nose. Because the noise is apparent only at exercise, the horse should be exercised after suture placement to determine if the alar fold is the cause of the problem.

Treatment of flaccid or redundant alar folds consists of bilateral resection of the fold. This procedure can be performed either through the external nares’ or by incising the lateral alae of the external nares. Incising the alae facilitates resection of the alar fold, but the resulting scar may be undesirable in show horses.

The patient is anesthetized and positioned in either dorsal or lateral recumbency. Dorsal recumbency provides adequate access if the procedure is performed through the external nares. Lateral recumbency provides the best exposure to the alar fold if the alae of the external nares are incised. The resection involves incising the alar fold caudal to the alar cartilage on the lateral wall of the nasal cavity to the rostral end of the ventral concha (Fig. 42-2). A second incision is directed caudally along the medial attachment of the alar fold to join the first incision. Approximately 2 cm of the rostral end of the ventral nasal concha is removed with the alar fold. Profuse hemorrhage may occur once the cartilage has been incised. A 22.5-cm curved Rochester-Carmalt forceps can be used as a guide for the incisions and to control hemorrhage (Fig. 42-3). Because ligation of bleeders is almost impossible when the approach through the external nares is used, hemostasis is achieved by closure of the incision using a simple-continuous suture pattern with size 0 absorbable suture material, commencing at the caudal limit. Healing is usually complete within 10 to 12 days, at which time the horse can return to work.

**Figure 42-2.** Resection of an alar fold. The dashed line represents the first incision, which extends caudally from the alar cartilage to the rostral end of the ventral concha. The dotted line represents the second incision.

**Figure 42-3.** Resection of an alar fold. Long, curved forceps are used to control hemorrhage and act as a guide for incisions. A, alar fold; B, incised edges of alae; C, alar cartilage.

**DISEASES OF THE NASAL CAVITY**

The most common clinical signs of nasal cavity disease are nasal stertor and unilateral nasal discharge and can include a fetid odor and facial distortion. Endoscopy or radiography or both are usually required for diagnosis.

**Facial Fractures**

Facial fractures involving the paranasal sinuses and nasal cavities are common and result from direct trauma. Fractures of the paranasal sinuses and nasal cavity most commonly involve the nasal and frontal bones but may also involve the maxillae and lacrimal bones.

Diagnosis of fractures of the paranasal sinuses and nasal cavity is based on history, clinical examination, and radiography. Radiographs of the skull should always be taken to assess the severity of the fracture, but the extent and degree of displacement of the fracture fragments may be more readily determined by palpation.

Even though the skin may be intact, these fractures should be considered open, because penetration of the sinus and nasal mucosa usually occurs. Reconstructive surgery should be performed as soon as it is feasible, because primary open reduction provides the best cosmetic results. Some facial fractures of the paranasal sinuses and nasal cavity heal spontaneously; however, failure to treat them may result in chronic sinusitis, bone sequestra, nonhealing wounds, facial deformity, and secondary nasal septal thickening or necrosis.

Many different reconstructive techniques have been described for facial fractures of the paranasal sinuses and nasal cavity. Procedures are performed with the patient anesthetized and positioned in lateral recumbency. Large, slightly curved or S-shaped incisions extending beyond the margins of the fracture are used to expose the traumatized area. Attempts should be made to preserve the periosteal attachments to the fragments. The fracture site is thoroughly debrided and irrigated to remove blood clots and debris.
Detached bone fragments devoid of periosteum can be thoroughly cleansed and replaced, but there is the possibility of eventual sequestration. If a paranasal sinus is involved, it should also be thoroughly lavaged to remove blood clots, small bone fragments, and other debris. Some small fractures may be elevated with a thin osteotome or a narrow periosteal elevator, whereas large fragments require other techniques to elevate them into position. The temporary use of orthopedic screws in the fragment and the use of holes drilled in solid bone adjacent to the fracture for insertion of a Langenbeck elevator have been described to assist in elevating the fragments into their normal anatomic position (Fig. 42-4). The use of suture material depends on the stability of the fractured fragments after reduction. Unstable fragments can be held in position using 20- to 22-gauge wire or size 1 monofilament absorbable sutures placed strategically through small holes drilled into the fragment and parent bone.

The incision is closed in two layers. The periosteum is re-apposed when using an absorbable suture. The use of a simple-continuous intradermal suture pattern to re-appose the skin edges has been reported to provide the best cosmetic results, but skin staples are faster and are also very cosmetic. A pressure bandage placed over a nonadherent dressing is recommended for 3 to 4 days to protect the area and minimize postoperative swelling. Systemic antibiotic therapy should be continued for 5 to 6 days.

A serosanguineous nasal discharge may be present for 1 to 2 weeks postoperatively. If this drainage continues, however, it may indicate the presence of a sequestrum or sinusitis. For additional information on facial fractures, see Chapter 103.

Nasal Septum Diseases

Diseases of the nasal septum are relatively rare and may cause thickening, malformation, or deviation of the septum. Specific diseases include cystic degeneration, malformation of normal tissue (hamartoma), abscess, traumatic thickening and necrosis secondary to septal fracture, longitudinal deviation of the incisive bones and nasal septum, and neoplasms. All of these lesions may produce similar clinical signs, such as decreased airflow or complete obstruction unilaterally, nasal stertor, nasal discharge, and occasionally facial distortion. Endoscopy, radiography, and computed tomography are useful to determine the exact site, extent, and nature of the involvement.

Some of these conditions may improve with removal of the nasal septum. Resection of the nasal septum may involve removal of a small portion or the majority of the septum. Incising the lateral alae of the nostril is the best approach for localized lesions of the rostral aspect of the septum, whereas a subtotal resection of the nasal septum or an alternative resection technique is used when the majority of the septum is involved.

Because of the likelihood of profuse hemorrhage during surgery, it is advisable to identify a suitable blood donor and collect 4 to 8 L of blood before surgery in case a blood transfusion becomes necessary. In addition, the administration of large volumes of intravenous fluids during surgery may be necessary to help alleviate hypotension. The most effective method of controlling hemorrhage is to use a nasal tampon after surgery.

The surgery is performed with the horse anesthetized and positioned in lateral recumbency. An airway should be established via a tracheotomy and the anesthetic delivered through it. The surgery for subtotal resection begins by making an 18-mm trephine hole on the bridge of the nose to gain access to the caudal portion of the septum. The center for this opening is located just rostral to the frontal sinuses where the nasal bones begin to diverge (see Fig. 42-1, D). A curved incision is made through the skin and periosteum, and the periosteum is reflected to provide exposure for the trephine. The nasal septum is easily identified once the bone plug has been removed and the mucosa has been incised. Doyen intestinal forceps or other suitable straight forceps are placed vertically on the nasal septum and they act as a guide for making the caudal incision in the septum. The rostral division in the nasal septum is performed by making a curved incision with a scalpel, starting from the ventral aspect of the septum and extending in a dorsocaudal direction, leaving at least 4 to 5 cm of the rostral septum to support the alar cartilages and external nares. A guarded chisel is used to incise the dorsal and ventral attachments of the nasal septum, and they act as a stop for the guarded chisel when severing the dorsal and ventral attachments of the nasal septum, and they act as a guide for making the caudal incision in the septum. The forceps act as a stop for the guarded chisel when severing the dorsal and ventral attachments of the nasal septum, and they act as a guide for making the caudal incision in the septum. The rostral division in the nasal septum is performed by making a curved incision with a scalpel, starting from the ventral aspect of the septum and extending in a dorsocaudal direction, leaving at least 4 to 5 cm of the rostral septum to support the alar cartilages and external nares. A guarded chisel is used to incise the dorsal and ventral attachments of the septum to the forceps. The caudal incision is made with a narrow osteotome immediately rostral to the Doyen forceps. The septum is then grasped through the external nares with heavy Vulsellum forceps and removed.

Figure 42-4. Fracture of the nasal and frontal bones. The holes in the parent bone adjacent to the fracture were made to insert a Langenbeck elevator to raise the fragment into its anatomic position. Interrupted stainless steel sutures were used to stabilize the fragment (black arrows).
Obstetric wire can be used instead of a guarded chisel to sever the dorsal and ventral attachments of the nasal septum. This causes less trauma and hemorrhage. Another advantage of this technique is removal of more of the ventral aspect of the septum than with the guarded chisel. When using obstetric wire for a subtotal resection, the caudal incision is made before the incisions of the dorsal and ventral attachments. The obstetric wire is threaded through the trephine opening on either side of the septum to the external nares. To incise the ventral attachment, the obstetric wire has to be forced to the most ventral aspect of the caudal septal incision. The septal attachments are severed easily with obstetric wire, so care should be taken not to incise beyond the rostral incision of the septum. Digital palpation or visual inspection using a flexible endoscope can be used to determine if all of the ventral attachment of the nasal septum has been removed. Ferris-Smith rongeurs can be used to remove the remaining portions.

An alternative technique has been described to remove the remainder of the nasal septum (see Fig. 42-5). The differences between this technique and the subtotal resection are as follows: the caudal incision is made at a 60-degree angle to the nasal bones in a dorsocaudoventral direction, the entire ventral septal attachment is incised up to the rostral incision, and the dorsal and ventral incisions are created by using obstetric wire. The obstetric wire is passed through the ventral meatus around the caudal aspect of the nasal septum and back through the opposite nasal passage to incise the ventral attachment. This is accomplished by passing the wire through the ventral nasal meatus into the nasal pharynx, and retrieving the wire through the opposite side using a rat-tooth forceps passed through the biopsy channel in a flexible endoscope. Another instrument that can be used to retrieve the wire is a long flexible grasping forceps (see Chapter 44). For the dorsal incision, the obstetric wire is threaded through the trephine opening on either side of the septum to the external nares. The caudal incision is made at a 60-degree angle to the nasal bones using a long narrow osteotome or a grooved cutting instrument fashioned from a standard wide-tipped screwdriver. The tip of the screwdriver is ground concave and the edges are rounded so that the cutting edge sits better on the septum, reducing trauma to the nasal conchae.

Packing the nasal cavity with sterile cotton roll gauze controls hemorrhage. Excessive packing of the nasal cavity may cause the nasal tampon to extend into the nasopharynx, where it may be inhaled or swallowed. The end of the gauze should be secured to the skin of the nares to prevent inadvertent removal of the pack.

The skin and periosteal incisions are closed in a routine manner. A tracheotomy tube is placed immediately after extubation.

Aftercare includes the use of systemic antibiotic therapy for 5 to 6 days. The nasal packing may be removed after 48 or 72 hours. The nasal cavity should be flushed daily with warm physiologic saline to remove dried blood, debris, and tissue fragments. Complete healing of the septal incisions occurs within approximately 4 to 6 weeks.

The prognosis for restoring normal function is guarded. Complications such as formation of excessive granulation tissue of the caudal septal stump or adhesions to the nasal conchae with subtotal resection may result in a persistent noise or exercise intolerance. Development of the technique that removes additional parts of the caudal septum has minimized these complications. Excellent cosmetic results can be expected except in foals younger than 6 months and in some Standardbreds, in which flattening of the bridge of the nose may occur even when adequate cartilage is left for support.

Ethmoid Hematoma

Ethmoid hematomas are well-encapsulated masses originating in or around the ethmoid labyrinth or occasionally from the paranasal sinuses. The cause is unknown, but hemorrhage occurs in the submucosa of an endoturbinate.
or a sinus, causing the mucosa to stretch and thicken, forming the capsule of the hematoma. An enlarging lesion of the ethmoid labyrinth can extend dorsally into the frontal sinus or ventrally into the sphenopalatine sinus by disrupting the tectorial plate. It may further extend into the maxillary sinus and nasal cavity as it enlarges.

In gross appearance, an ethmoid hematoma has a smooth, glistening surface that may be mottled or green-tinted. Histologically, the lesions are very distinct. The capsule is composed of respiratory epithelium and fibrous tissue. The stroma contains blood, fibrous tissue, macrophages, and giant cells with deposits of hemosiderin and occasionally calcareous deposits. Progressive ethmoid hematomas have been reported in horses ranging from less than 1 year to 20 years of age, with a mean of 9.9 years. Although the condition occurs mostly in middle-aged male horses, it has also been described in young horses and in females; one report found no statistical difference between the occurrence in males and females. Most cases have been reported in Thoroughbreds, but an ethmoid hematoma also has been described in other breeds.

The most consistent clinical sign is a mild, intermittent, unilateral epistaxis that is usually spontaneous but may occur with exercise. An abnormal respiratory noise may be heard when the hematoma extends into the nasal cavity or causes a distortion of the paranasal sinuses. Other possible clinical signs include malodorous breath, facial swelling, head shyness, and head shaking. A tentative diagnosis can be made from the history, clinical signs, and endoscopic and radiographic findings. A definitive diagnosis is made by histologic examination of the tissue. Endoscopic findings early in the development of an ethmoid hematoma can include a trickle of blood from the ethmoidal meatus or middle meatus, and a discoloration or enlargement of the great ethmoturbinate. Hence, small lesions of the sinuses may not be detected endoscopically. However, as the condition progresses, a greenish yellow to purplish red mass may be seen obscuring the fundus of the nasal cavity (Fig. 42-6) or the entire nasal passage.

The most characteristic radiographic abnormality is a smooth, discrete, rounded density in the frontal or maxillary sinus; however, radiographic changes may include fluid lines or diffuse opacities of the sinuses. Computed tomography (CT) is useful to determine the exact location and extent of the hematoma involvement (Fig. 42-7), because it provides a cross-sectional view of the skull, which eliminates the superimposition of the paranasal sinuses and nasal cavity that occurs with the lateral radiographic projection.

Differential diagnoses include other conditions that may result in persistent or intermittent epistaxis or blood-stained nasal discharge, such as ulcerative or fungal rhinitis; foreign body; ethmoidal neoplasia; mycosis or neoplasia of the guttural pouch; skull fracture; neoplasia, infection, or cyst of the paranasal sinuses; pulmonary abscess or neoplasm; or infectious pleuropneumonia.

The goal of surgery is removal of the mass and destruction of its origin. The surgical approach for removal depends on mass size and location. Lesions limited to the fundus of the nasal cavity and less than 5 cm in diameter can be treated transendoscopically using a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser in a standing patient or by intralesional injection of formalin (see later).
Lesions that are large and extend into the nasal passage or sinuses are best approached via bone flap techniques, gaining access to the origin of the lesion with the horse anesthetized and in lateral recumbency. These techniques can be used to expose the maxillary sinus, frontal sinus, and nasal cavity. One of these techniques, the frontonasal bone flap, gives improved access and has more versatility than other approaches, especially if there is involvement in both the nasal cavity and the frontal sinus. It also allows the creation of a large endoscopic portal to the sinuses, which permits future evaluation for recurrence and treatment with the Nd:YAG laser in a standing patient (Fig. 42-8).

Intraoperative hemorrhage is an expected complication from damage to the normal nasal or sinus mucosa, to the ethmoturbinates, or from the ethmoid hematoma itself. Various techniques have been described to provide hemostasis during surgery, such as bilateral carotid artery ligation, roll gauze packing, epinephrine-soaked gauze packing, vascular clips, lavage with sterile physiologic saline solution (cold or ice slush), and liquid nitrogen spray. Cryosurgical removal of the lesion is reported to lower the incidence of recurrence, but this requires adequate exposure of the base as well as a relatively blood-free surgical field. If the lesion is large, sequentially freezing and removing segments of the mass until the origin is frozen helps to minimize hemorrhage. The use of thermocouples controls the depth of freezing, especially in the ethmoid labyrinth to help protect the cribriform plate. Single freezes of −30°C are suggested to avoid damage to normal structures. The use of the Nd:YAG laser for removal of the lesion has been reported to decrease the amount of hemorrhage and the chance of recurrence.32,35

Thorough presurgical planning reduces delays and significant blood loss. In preparation, besides collecting 4 to 8 L of blood for a possible transfusion, it is advisable to administer at least 10 L of intravenous fluids immediately before the induction of anesthesia, and to continue to administer fluids throughout the surgery, thereby alleviating hypotension associated with blood loss. The amount of hemorrhage is usually minimal until disruption of the base of the lesion or other highly vascular structures such as the tectorial plate of the ethmoid labyrinth or the conchal wall of the conchofrontal sinus. Frequently, it is necessary to invade these structures to gain access to the base of the lesion.

Regardless of the removal technique, the most effective method for controlling hemorrhage is firm packing of the sinus or nasal cavity with sterile, cotton roll gauze after surgery. The bone flap is closed in a routine manner. Before closure of the flap, a catheter is placed through the adjacent bone to simplify lavage of the sinus once the pack has been removed. To facilitate removal of the gauze, it can exit either from an aperture on the free edge of the bone flap or through the nasal cavity. The end of the gauze should be secured to the skin of the nares to prevent inadvertent removal of the pack.

Broad-spectrum systemic antibiotics are started before surgery and continued for 3 to 4 days. Administering a sedative and analgesic facilitates removal of the packing 48 to 72 hours after surgery. The use of an indwelling lavage system decreases labor and reduces the horse’s resentment of the daily treatment. Lavage of the sinus is helpful in removing exudate, blood clots, and tissue debris, but its effectiveness depends on having adequate drainage through either the nasomaxillary opening or a surgically created opening into the nasal cavity (see later). The horse should be confined to stall rest with only hand-walking for at least 3 weeks. It is common to see fungal and necrotic tissue plaques develop on devitalized mucosal tissues for up to 60 days after surgery, but these usually resolve with no further treatment.

Prognosis is unfavorable without treatment because the lesion is progressive and eventually causes obstruction and dyspnea.32 The chance of recurrence after routine surgical removal is relatively high (approximately 43%). Clients should be advised of the importance of periodic endoscopic examinations after surgery to detect recurrence, so that prompt therapy can be instituted. Because bilateral involvement does occur, endoscopic examination of both nasal passages should always be performed. The use of the Nd:YAG laser on recurrent lesions shows promise in preventing the future recurrence, especially when access to the sinuses via the nasal passage has been provided.

Reported ablation techniques for the treatment of progressive ethmoid hematomas in a standing, sedated horse include transendoscopic use of the Nd:YAG laser, intraslesional formaldehyde injection, and cryotherapy. The Nd:YAG laser is effective in the standing horse for lesions less than 5 cm in diameter when limited to the nasal fundus only. Therefore, the technique is not applicable for lesions extending into the sinuses. Several laser applications are usually required to ablate the lesion successfully. Lesions are
The principles of therapy for primary sinusitis are to provide adequate drainage and to use the appropriate systemic antimicrobial agents based on antibiotic culture results and sensitivity testing. Drainage may be enhanced by lavaging the sinus once or twice daily. Drainage and lavage are accomplished by either placing an indwelling catheter percutaneously into the maxillary sinus (see the preceding paragraph on sinocentesis for the procedure) or by using a small, sterile, flexible plastic stallion catheter through a trephine opening in the frontoconchal sinus. The skin over the site for entering the frontoconchal sinus is anesthetized with 2% Carbocaine (see later). A small, slightly curved incision is made through all layers of tissue to the bone. The skin incision should be larger than the opening in the sinus to facilitate closure. The tissues are reflected from the bone together, and a circular opening is made using a 19-mm
Cault trephine. The exudate is most efficiently removed from the sinus by inserting a 6.6-mm (OD) sterile, flexible plastic stallion catheter into the frontoconchal sinus and flushing with a mild salt solution (1.2 ounces of salt per gallon of water) via a sterile stomach pump.

Primary paranasal sinusitis usually resolves with systemic antibiotic therapy and lavage, but when the exudate becomes inspissated in the ventral conchal sinus, surgical treatment becomes necessary.43,44 This condition should be suspected when a primary paranasal sinusitis does not resolve with systemic antibiotics and lavage. Other features of a ventral conchal sinusitis are as follows:

1. The radiographic presence of a soft tissue density over the roots of the superior 4th premolar (108/208), and the 1st (109/209) and 2nd molars (110/210)
2. Distortion of the sinus, seen as a narrowing of the nasal passage caused by an accumulation of inspissated exudate in the ventral conchal sinus

Surgical treatment includes removal of the exudate from the ventral conchal sinus and providing additional drainage if necessary. The ventral conchal sinus can be accessed via a maxillary bone flap or by trephining the frontal sinus in the standing horse (see later).

Secondary sinusitis may be caused by dental disease, facial fractures, granulomatous lesions, or neoplasms. Identifying the cause of sinusitis radiographically can be very difficult with exudate in the sinus. Removal of the exudate via lavage through a trephine opening into the sinus may enhance the radiographic and endoscopic examination of the sinus. After removal of the exudate, the frontoconchal and caudal maxillary sinuses can be reexamined either radiographically or endoscopically. The skin is closed temporarily with skin staples to allow daily flushing. Dental disease is the most common cause of secondary sinusitis,1,43,44 (see Chapter 30). Secondary sinusitis is generally more difficult to treat and requires surgical intervention to remove the underlying cause (see "Surgical Approaches to the Paranasal Sinuses," later).

Paranasal Sinus Cysts

Occurrence of paranasal sinus cysts is well documented.46-50 The exact etiology and pathogenesis are unknown, but the cysts are suspected to be of dental origin.53 There is some evidence that these cysts may have a common origin with ethmoid hematomas.55 The condition is usually seen in horses ranging in age from nursing foals to young adults, but it is also seen in adult horses. The most common clinical features are dyspnea, facial swelling, and nasal discharge. As the cysts expand, the pressure causes distortion of the ventral nasal concha, the normal internal structures of the sinus, and the maxilla, resulting in obstruction of the common nasal meatus and possible deviation of the nasal septum and facial deformity. The cysts are typically filled with a yellow, viscous fluid unless they become secondarily infected. There have been no reports of spontaneous regression. Surgical management consists of removing the cysts completely, establishing drainage, and repelling any teeth that may be involved. Complete exposure of the sinus can be provided only via a bone flap technique.36 Although the prognosis is usually guarded because of the accompanying distortion of the ventral nasal concha and nasal septum, there are reports of regression of the nasal obstruction and facial deformity after surgery in young, growing horses.48,50

Neoplasia

The most common tumor of the paranasal sinuses is squamous cell carcinoma. Other invasive tumors reported include spindle-shaped sarcoma46; osteogenic sarcoma, lymphosarcoma, and a poorly differentiated carcinoma46; ethmoid carcinoma;52; hemangiosarcoma; and adenocarcinoma.53 Solid, noninvasive neoplasms such as fibroma,53 osteoma,54,55 and ameloblastic odontoma56 have been reported. Useful clinical signs that may aid in differentiating neoplasia from other sinus diseases are malodorous breath without evidence of dental disease and radiographic evidence of widespread bone destruction. The prognosis is generally unfavorable unless the neoplasm is a solid noninvasive tumor, because the majority are malignant.53

Surgical Approaches to the Paranasal Sinuses

Surgical access to the paranasal sinuses can be obtained by either trephination or bone flap techniques.30,42 The bone flap techniques are superior to trephination because they provide better exposure, visualization, and access for surgical manipulation within the sinuses, and they eliminate the need for multiple trephine openings. The bone flap technique was first described for exploration of the maxillary sinus,46 but the technique can be used for the frontal sinus and nasal cavity.

trephtnination is the traditional approach for surgical access to the paranasal sinuses. It is useful for diagnostic and therapeutic access to the sinuses. The approximate sites for trephination of the frontal, caudal, and rostral maxillary sinuses are shown in Figure 42-1. The age of the horse should be considered when selecting the site for trephination of the maxillary sinus. The alveoli of the caudal three cheek teeth form the ventrolateral wall of the sinus. In horses 3 years old and younger, the alveoli lie immediately under the osseous infraorbital canal. As the horse ages and the teeth advance, the sinus becomes larger. The trephination sites usually heal within 3 to 4 weeks with minimal blemish.

For the maxillary bone flap (Fig. 42-9), the rostral margin is a line drawn from the rostral end of the facial crest to the infraorbital foramen; the dorsal margin is a line from the infraorbital foramen to the medial canthus of the eye; the caudal margin is a line (parallel to the rostral margin) from the medial canthus of the eye to the caudal aspect of the facial crest; and the ventral margin is the facial crest. These boundaries provide maximal exposure of the maxillary sinus while protecting the vulnerable infraorbital canal and nasolacrimal duct.

Alternatively, for the frontonasal bone flap (Fig. 42-10), the caudal margin is a perpendicular line from the dorsal midline to a point midway between the supraorbital foramen and the medial canthus of the eye; the lateral margin begins
at the caudal margin 2 to 2.5 cm medial to the medial canthus of the eye and extends to a point approximately two-thirds the distance from the medial canthus of the eye to the infraorbital foramen; and the rostral margin is a perpendicular line from the dorsal midline to the rostral extension of the lateral margin. The estimated course of the nasolacrimal duct is a line from the medial canthus of the eye to the nasoincisive notch. In some horses, the rostral portion of the lateral margin has to be angled toward the midline to avoid the duct (see Fig. 42-10).

Once the boundaries of the area to be explored are determined, a skin incision is made along the rostral, ventral or lateral, and caudal borders. The incision is continued through the subcutaneous tissue to the periosteum, which is exposed and incised. The periosteum is reflected from the site of the proposed osteotomy incision approximately 5 mm.

The osteotomy can be performed using an oscillating bone saw, a pneumatic drill with a tapered burr, or an osteotome and mallet. The osteotomies should be beveled so that when the bone flap is replaced it will provide a more secure closure. Once the osteotomy has been completed on all three sides, the bone flap can be slowly elevated until it fractures along the fourth (or dorsal) side of the rectangle beneath intact tissue. The fracture can be controlled by steady, even pressure and the bone flap completely elevated to expose the area. Before closure, an indwelling lavage system is usually placed through the adjacent bone or a corner of the flap and secured to the skin to facilitate daily lavage. Closure is initiated by pressing the bone flap into its original position and by closure of the periosteum with 2-0 absorbable suture using a simple-continuous pattern. A simple-interrupted stainless steel or monofilament non-absorbable suture placed at each corner of the flap may occasionally be necessary to secure the flap to the parent bone, but these are frequent sites of fistula formation and should be avoided when possible. The subcutaneous tissue and skin are closed in routine manner. The skin incision usually heals rapidly with minimal scarring.

Frequently, creating a surgical opening into the nasal cavity is necessary to improve drainage. Identifying such a site in the conchofrontal sinus (Fig. 42-11) can be aided by passing a mare urinary catheter caudally in the dorsal meatus and feeling the catheter tip through the thin conchal portion of the sinus. The conchal wall is perforated using a curved forceps. The catheter is passed through the opening to aid in the placement of a seton drain threaded through the nasal cavity from the sinus. The site for establishing communication between the rostral maxillary sinus and the nasal cavity is located dorsally over the infraorbital canal in young horses and ventral to the canal in older horses. Caution should be used to prevent damage to the infraorbital canal. The use of a Seton drain helps maintain the patency of the newly created opening to the nasal cavity; a mushroom catheter is usually used instead of gauze or Penrose tubing with the bone flap technique. Once the Seton drain has been removed, the newly created opening may remain permanently open or it may close naturally; therefore, the Seton drain should not be removed until the underlying disease is resolved.
Gaining Surgical Access to the Ventral Conchal Sinuses

The ventral conchal sinus can be entered over the osseous infraorbital canal through the conchomaxillary opening in young horses or by penetrating the thin bony plate (see Fig. 42-11) below the osseous infraorbital canal in older horses. After removing the inspissated exudate, the nasomaxillary opening should be assessed for patency by flushing the sinus with saline and observing for nasal outflow. The medial or ventromedial wall of the sinus can be fenestrated to create an opening into the nasal passage if the nasomaxillary opening is not functional. Removal of inspissated exudate from the ventral conchal sinus has also been reported in the standing horse via a 19-mm trephine opening (see Fig. 42-1). The caudodorsal (bulla) wall of the ventral conchal sinus is identified by palpating ventral and slightly rostral to the trephine opening (see Fig. 42-1). The wall can be perforated with an index finger. The exudate is removed by inserting a 6.6-mm (OD) sterile, flexible plastic stallion perforated catheter into the ventral conchal sinus and flushing with a mild salt solution (1.2 ounces of salt per gallon of water) via a sterile stomach pump.

One of the most important aspects of the treatment of sinusitis is lavage of the sinus to remove exudate, blood, blood clots, or tissue debris. The effectiveness of the lavage depends on adequate drainage, either through a patent nasomaxillary opening or through surgically created openings into the nasal cavity. The frequency and volume are probably more important than the type of lavage solution. Sterile physiologic saline is as effective as antiseptic solutions in most cases and reduces irritation of the mucous membranes. The use of an indwelling lavage system decreases labor and reduces the horse’s resentment to daily lavage. Placing a sterile tube through a small trephine opening and pumping a mild salt solution through a sterile pump is a very simple, inexpensive method of flushing the sinuses (see treatment modalities under “Sinusitis,” earlier).

The use of systemic antibiotic therapy depends on the primary disease and should be based on bacterial cultures and antibiotic sensitivity results. Feeding the horse on the floor enhances drainage and reduces contamination by hay and dust. Gauze plugs placed in trephine openings or a protective hood made from stockinette also reduces contamination and protects surgical sites in the facial area.

### TEMPORAL AND PHYSIOLOGY

The pharynx is a musculomembranous tubular structure unsupported by bone or cartilaginous matrix. It has different roles during breathing, deglutition, and vocalization. The pharynx extends from the caudal end of the nasal cavity to the larynx and is equally divided by the soft palate to form the nasopharynx dorsally and the oropharynx ventrally. During normal breathing, the caudal free margin of the soft palate intimately contacts the subepiglottic tissue at the base of the equine larynx (Fig. 43-1) and prevents communication between the oropharynx and nasopharynx. The nasopharynx is attached to the pterygoid, palate, and hyoid bones and to the laryngeal, cricoid, and thyroid cartilages by muscles, which cause dilation and constriction of the nasopharynx. Although the nasopharynx is not directly supported by cartilage or bone, it must withstand large changes in intraluminal pressures (from 24 to 50 cm water) that occur at varying airflow velocities (up to 90 L/s), with minimal changes in diameter. It does this through muscular contraction.

Several groups of muscles alter the size and configuration of the nasopharynx, including the muscles that move the tongue, insert on the hyoid apparatus and larynx, and regulate soft palate position. Some muscle contractions alter the position of the hyoid apparatus. Specifically, ventral displacement of the basihyoid increases nasopharyngeal size and stability by increasing the diameter or decreasing compliance of the nasopharynx. The relevant musculature...
can be classified as intrinsic or extrinsic to the nasopharynx. The **intrinsic** muscles, which include those of soft palate and nasopharyngeal musculature, insert on the mucosa or the confined walls and roof of the nasopharynx. The **extrinsic** muscles include those of the larynx and the hyoid apparatus (musculature not part of the nasopharyngeal walls that affect either the position of the basihyoid bone or larynx).

**Intrinsic Musculature**

The intrinsic musculature contributes to the stability of the nasopharynx mainly by timely muscular contractions that tense and dilate the pharyngeal wall (Fig. 43-2). The floor of the nasopharynx is formed by the soft palate extending caudally from the hard palate to the base of the larynx. The soft palate consists of oral mucous membrane that contains the palatine glands and their ductile openings, palatine aponeurosis, palatinus and palatopharyngeus muscles, and nasopharyngeal mucous membrane. The palatine aponeurosis is formed by expansion of the tendon of the tensor veli palatini muscle. This aponeurosis attaches to the caudal margin of the hard palate. It is thick cranially and very thin caudally, where the soft palate is more muscular. The caudal free margin of the soft palate continues dorsally on either side of the larynx, forming the lateral pillars of the soft palate. Muscle fibers of the palatinus muscle course beneath the nasopharyngeal mucosa and extend along the pillars of the soft palate. These pillars unite dorsally, forming the palatopharyngeal arch.

The position of the soft palate is determined by the coordinated function of four muscles (Fig. 43-3, and see Fig. 43-2): the tensor veli palatini, levator veli palatini, palatinus, and palatopharyngeus muscles. The tensor veli palatini muscle is innervated by the mandibular branch of the trigeminal nerve, and the other three are all innervated by the pharyngeal branch of the vagus nerve. The **levator veli palatini** muscle arises from the muscular process of the petrous part of the temporal bone and the lateral lamina of the auditory tube and passes along the lateral wall of the nasopharynx to insert within the soft palate dorsal to the glandular layer. This muscle elevates the soft palate during swallowing, closes the nasopharynx, and facilitates oral ventilation in nonobligate nasal breathers. The **palatineus** muscle consists of a paired fusiform muscle that originates at the caudal aspect of the palatine aponeurosis and courses through the middle of the soft palate, just beneath the nasal mucosa, to ramify...
in the caudal free margin of the soft palate. The *palatopharyngeus* muscle arises from the palatine aponeurosis (lateral to the palatine muscle attachment) and from the palatine and pterygoid bones. The fibers continue caudally on the lateral wall of the pharynx and partially insert into the upper edge of the thyroid cartilage. The remainder of the muscle continues dorsally and inserts at the median fibrous raphe. The palatini and palatopharyngei muscles shorten the soft palate and depress it toward the tongue. The *tensor veli palatini* muscle is a fusiform muscle that originates at the muscular process of the petrous part of the temporal bone, pterygoid bone, and lateral lamina of the auditory tube and travels rostroventrally along the lateral wall of the nasopharynx lateral to the *levator veli palatini*. The tenon courses around the hamulus of the pterygoid bone and ramifies in the palatine aponeurosis. This muscle tenses the rostral aspect of the soft palate by using the hamulus as a pulley and retracts the soft palate away from the dorsal pharyngeal wall, expanding the nasopharynx and slightly depressing it ventrally during inspiration.

The final intrinsic muscle of the nasopharynx is the *stylopharyngeus*, which is divided into two parts. The *stylopharyngeus rostralis* originates from the medial surface of the rostral end of the stylohyoid bone and inserts on the pharyngeal raphe. It is a pharyngeal constrictor that is not stimulated during exercise, so it will not be discussed further. The *stylopharyngeus caudalis* is a pharyngeal dilator muscle that originates from the medial aspect of the caudal third of the stylohyoid bone and courses ventrally and rostrally to attach on the dorsolateral wall of the pharynx (Fig. 43-1), which attaches to the hyoid bone at the base of the cartilage and to the caudal part of the hyoid arch. Its innervation is from branches of the hypoglossal nerve and is responsible for tension on the roof of the nasopharynx (Fig. 43-4) that helps it resist collapsing with inspiratory pressure.

The blood supply to the soft palate is derived from the lingual and facial trunks, and maxillary artery and venous drainage occurs via the accompanying veins. The lymph vessels drain toward the retropharyngeal lymph lymph nodes. The afferent innervation from branches of the trigeminal, glossopharyngeal, and vagus nerves arises from pressure, mechanical, and temperature receptors lining the mucous membrane of the nasopharynx, including the soft palate.

**Extrinsic Musculature**

The extrinsic muscles contribute to the respiratory patency of the nasopharynx by increasing its diameter or by increasing the stability of the soft palate, or both. In dogs and humans, ventral displacement of the bony pharynx results in increases in the nasopharynx diameter. The genioglossus muscle is a fan-shaped extrinsic tongue muscle that originates within the median plane of the tongue and attaches to the oral surface of the mandible, caudal to the symphysis (Fig. 43-3). Contraction of the genioglossus muscle protracts the tongue and pulls the bony pharynx rostrally. In horses, this activity was once thought to result in an increase in nasopharyngeal diameter and improvement in airway patency. This was the hypothesis behind using a tongue-tie in racing horses, which has been disproved by recent studies. Computed tomographic imaging showed no measurable improvement in nasopharyngeal diameter by using a tongue-tie in normal horses. Likewise, no improvement in airway patency during treadmill exercise was shown by using a tongue-tie in normal horses. Contraction of muscles that insert on the hyoid arch increases upper airway size and stability by increasing the diameter and stiffness of the nasopharynx. The rostrohyoid and caudohyoid muscle groups exert rostral and caudal forces, respectively, on the hyoid apparatus. The geniohyoideus is a rostrohyoid muscle that originates, in conjunction with the genioglossus, on the medial surface of the mandible near the symphysis and inserts on the basihyoid bone. Its action draws the hyoid apparatus rostrally. The sternohyoideus and sternothyroideus muscles are caudohyoid muscles that originate on the sternal manubrium and extend cranially. The sternothyroideus inserts on the caudal aspect of the thyroid cartilage, and the sternohyoideus muscle inserts on the basihyoid bone and lingual process of the hyoid apparatus. Contraction of these muscles results in caudal traction on the hyoid apparatus and larynx. In dogs and humans, muscles that put rostral traction on the basihyoid bone work in a coordinated fashion with muscles that apply caudal traction, and the sum of these vector forces is a net ventral displacement of the basihyoid bone. This motion increases the angle at the cratothyoid–stylohyoid joint, increasing the dorsal ventral dimension of the nasopharynx. In doing so, the lateral walls of the nasopharynx expand slightly and become taunt. Although this has not been demonstrated conclusively in horses, dysfunction of the strap muscles (sternohyoideus and sternothyroideus) in horses has been shown experimentally to increase the upper airway pressure at exercise. This suggests that nasopharyngeal impedance is increased by dysfunction of these extrinsic muscles.

Another extrinsic muscle known to increase the patency of the nasopharynx is the hyoepiglotticus muscle (see Fig. 43-3), which attaches to the hyoid bone at the base of the epiglottis and, during its contraction, pulls the epiglottis ventrally toward the base of the tongue, thereby increasing the ventral dimension of the rima glottidis. The hyoepiglotticus muscle is the only muscle that inserts on the epiglottis. Finally, the thyrohyoideus muscle, which extends from the lateral lamina of the thyroid cartilage to the caudal aspect of the thyrohyoid bone (see Fig. 43-4) was thought to move the larynx rostrally only during deglutition. However, resection of this muscle disrupts the normal stability of the nasopharynx during exercise, resulting in dorsal displacement of the soft palate (DDSP). Therefore, the mechanism of action of the thyrohyoideus muscle is to enhance soft palate stability during exercise by moving the larynx rostrally so that the thyroid cartilage rests more dorsal and rostral in relation to the basihyoid. The geniohyoideus, genioglossus, and hyoepiglotticus muscles are all innervated by the hypoglossal nerve; whereas sternohyoideus and sternothyroideus muscles receive motor innervation from branches of the first and second cervical nerves. Although it has been reported that the thyrohyoid branch of the hypoglossal nerve is responsible for innervation of the thyrohyoideus muscle, recent investigations suggest that the pharyngeal branch of the vagus is responsible for this innervation. Arterial blood supply to the pharynx is provided by the common and external carotid arteries and the lingual arterial trunk. Venous drainage is provided by the accompanying veins.
toward the retropharyngeal and cranial cervical lymph nodes.\textsuperscript{2} The trigeminal, vagus, and glossopharyngeal nerves provide afferent sensory innervation to the nasopharyngeal mucosa.

ANATOMIC DISORDERS OF THE NASOPHARYNX

Nasopharyngeal Cicatrix

Nasopharyngeal cicatrix was a condition first reported as being more commonly seen in aged female horses,\textsuperscript{17} but more recent data suggest only a slight predisposition for mares (60\% of 87 horses).\textsuperscript{18} Affected animals range in age from 5 to 29 years.\textsuperscript{17,18} This anomaly is seen almost exclusively in hot climates (mostly in eastern and southern Texas, with occasional reports from Mississippi, Louisiana, Oklahoma, and Florida) in horses kept on pasture. An environmental allergen is thought to lead to nasopharyngeal inflammation and subsequent damage to the nasopharyngeal and laryngeal mucosa and submucosa. Secondary healing results in a web of nasopharyngeal scarring that reduces the diameter of the nasopharynx, or restricts its function when severe\textsuperscript{17,18} (Fig. 43-5). In nearly 95\% of reported cases, deformed epiglottic, arytenoid, or medial cartilage of the gullet pouch opening is seen\textsuperscript{17,18} (Fig. 43-6). Because of the larger cross-sectional area of the nasopharynx in comparison to the rima glottidis and extrathoracic trachea, only severe scarring of the nasopharynx causes functional abnormalities. The degree of involvement of other structures determines clinical signs.

Clinical signs for this condition include upper respiratory noise and exercise intolerance, with dysphagia rarely seen. The airway sounds may be variable, depending on whether nasopharyngeal scarring results in DDSP or arytenoid chondritis. Involvement of one or both of the arytenoid cartilages is the most common reason for exercise intolerance and respiratory noise. The degree of performance interference depends on the athletic demands and degree of ventilation interference.

The diagnosis is made by endoscopic examination. In the earliest stages, hyperemic mucosa is observed; there may also be yellow or discolored areas (plaques) on the pharyngeal walls, even in areas where a cicatrix does not form.

Figure 43-4. Schematic of the intrinsic muscles that form the wall and roof of the nasopharynx. Note that contractions of the stylopharyngeus caudalis support the roof of the nasopharynx. Also, compare Fig. 40-5, A and B. Note the direction of the stylopharyngeus caudalis fibers and therefore the direction of its contractions.

Figure 43-5. Endoscopic photograph of a nasopharyngeal cicatrix in a horse, characterized by scar formation across the floor of the nasopharynx. (Courtesy P. Rakestraw, Texas A&M University.)

Figure 43-6. Endoscopic photograph of a nasopharyngeal cicatrix affecting the larynx and epiglottic cartilage. Note the deformation of right arytenoid cartilage, as well as scar formation across the floor of the nasopharynx. (Courtesy P. Rakestraw, Texas A&M University.)
The cicatrix can be limited to a local area or involve the entire circumference of the pharynx, and it usually includes one or more transverse bands of tissue located between the guttural pouch opening and the larynx (see Fig. 43-5). In 20% of the cases reported, one of the guttural pouch openings was involved in the cicatrix.17 Because this type of cicatrix is generally associated with epiglottic and arytenoid chondropathy (see Fig. 43-6), the anatomic integrity of these structures should be assessed as well as the position of the soft palate.

As soon as the diagnosis is made, the horse should be removed from the pasture and anti-inflammatory therapy initiated.18 Horses housed in a dry lot or box stall do not seem to be affected by this disease. If the cicatrix causes nasopharyngeal obstruction, it can be transected in two or three places under videoendoscopic guidance with the horse standing, using a diode or other appropriate laser. Although nasopharyngeal stenting has been reported, its use does not seem to have significant value.18,19 If airway obstruction is associated with chondritis, a permanent tracheostomy (as described in Chapter 46) should be performed. Partial arytenoidectomy in this heavily scarred environment leads to an inappropriate diameter of the rima glottidis during postoperative healing and, therefore, should not be performed.

**Nasopharyngeal Masses**

Nasopharyngeal masses occur rarely in horses. When masses are present in the nasopharynx, they usually are extensions of paranasal sinus, guttural pouch, or oropharyngeal diseases. However, primary masses involving the nasopharynx can include benign lesions such as fungal granulomas and cysts and neoplastic lesions such as lymphosarcoma and squamous cell carcinoma.20,22 Depending on the size and location of these masses, they may result in DDSP, dysphagia, or airflow obstruction. Therefore, clinical signs may include exercise intolerance, respiratory noise, nasal drainage, and weight loss. If the mass extends into the rostral nasopharynx or nasal cavity, uneven airflow can be detected at the nostril, and mucopurulent drainage may be present.

The diagnosis of nasopharyngeal masses is made by endoscopic examination on recognition of these clinical signs (Fig. 43-8). A thorough evaluation of adjacent structures (nasal cavity, paranasal sinuses, and guttural pouches) is imperative. Radiography and/or general anesthesia followed by oral manual or oral endoscopic examination may help identify masses extending into the oropharynx. A biopsy sample of the mass can be taken by sedating the horse and using uterine biopsy forceps (Richard Wolf Medical Instruments Corporation, Vernon Hills, Ill). Two or three samples can be taken with a small amount of local hemorrhage. A biopsy of the mass yields the critical information necessary for appropriately managing and treating the lesion.

Treatment is based on the extent of the lesion and the biopsy results. Surgical access to the nasopharynx is limited, and three main options are available: videoendoscopy-assisted laser resection, intraligamental injection of a necrosing pharmacologic agent (10% formaldehyde), and surgical attention through an oral approach or pharyngotomy. The author prefers the oral approach.

**Videoendoscopy-Assisted Laser Resection**

Videoendoscopy-assisted laser resection is performed as follows. The average 450-kg horse is sedated with a solution of detomidine (6 mg) and butorphanol (4 mg). One should err toward a smaller dosage of butorphanol, because some horses experience “head tics” that interfere with the surgical procedure using this medication. The videoendoscope is passed into the right nostril, and the mass is desensitized by applying 50 mL of a topical anesthetic solution (2% lidocaine or mepivacaine hydrochloride) and 10 mL of vasoconstrictive agent (0.15% phenylephrine) through the...
biopsy channel of the videoendoscope. The videoendoscope is withdrawn to the nasal cavity near the dorsal meatus, and local anesthetic is applied to desensitize this area and thus facilitate forceps manipulation. The videoendoscope is passed through the left nostril, and the bronchoesophageoscopic forceps are passed into the right nostril to grasp or otherwise facilitate access to the base of the mass. Using a diode (12 to 15 watts) or neodymium:yttrium aluminum garnet (Nd:YAG, 30 to 35 watts) laser, the base of the mass is incised with the laser. A large mass that cannot be removed nasally should be removed in smaller sections. Some masses must be reduced by intralesional injection prior to laser resection.

**Intralesional Injection**

Treatments by intralesional injection to induce chemical necrosis of the mass, or local treatment with antimicrobials or antifungal agents, can be used if mass resection is not possible. A polyethylene catheter is passed through the endoscope biopsy channel until it emerges from the biopsy port of the endoscope. A 16-gauge needle is attached to the tubing by removing the needle hub and securing the needle 5 to 7 mm into the tubing. The needle should fit tightly so that it will not dislodge during the injection. The horse is sedated before the injection as described earlier for the laser procedure. Fungal granulomas, such as seen in coccidioidomycosis, are treated with weekly intralesional injections of amphotericin B (100 mg of a 100 mg/mL preparation) combined with 3 mL of a 90% solution of medical-grade dimethyl sulfoxide (DMSO). In addition, potassium iodide (125 mL of a 20% sodium iodide solution IV, once a day for 3 days, followed by 30 g PO once a day for 30 days) is given after clinical remission or until signs of iodine toxicity (dry skin) are noted (see Merck Manual). Most masses, other than abscesses and polyps, are treated with repeated intralesional injection of 10% formaldehyde (10 to 20 mL). The masses are reinjected at 3- to 4-week intervals until resolution, or until the size has been reduced. After each treatment, the horse receives a 3- to 5-day course of phenylbutazone (1 mg/lb PO twice a day) or a similar nonsteroidal anti-inflammatory drug (NSAID).

Occasionally, pedunculated cysts or polyps originate near the gutteral pouch opening, obstructing the nasopharynx. These masses can be extracted with the horse under general anesthesia using laparoscopic instruments and videoendoscopic guidance.

**SURGICAL APPROACHES TO THE NASOPHARYNX OR OROPHARYNX**

The nasopharynx is best approached through nasal videendoscopy, although limited exposure can be obtained by a pharyngotomy with rostral retraction of the caudal free edge of the soft palate. The oropharynx also can be approached orally (see “Tension Palatoplasty” and “Thermal Palatoplasty,” later), orally after a mandibular symphysiotomy (see “Surgical Approaches” under “Cleft Palate,” later), and through a laryngotomy via incision of the cricothyroid ligament (see “Staphylectomy,” later).

Approaches to the oropharynx are performed with the horse under general anesthesia, and the surgical procedures are best performed using long instruments. The pharyngotomy allows access to the caudal third of the soft palate for cleft repair or removal of associated cysts or masses. Likewise, a pharyngotomy provides access to remove a subepiglottic mass or cyst, but a laryngotomy approach has less morbidity, making it preferable. The major disadvantages of the pharyngotomy approach are its limited exposure and the possibility of damaging the hyoepiglotticus muscle (see Fig. 43-1) or its innervation. This can result in significant disability, as epiglottic retroversion during exercise is the consequence of neuromuscular damage to the hyoepiglotticus muscle (see Chapter 44). Therefore, the pharyngotomy approach should be reserved for conditions that cannot be approached through the oral route or a laryngotomy.

With the horse under general anesthesia and in dorsal recumbency, the ventral aspect of the basihyoid bone and thyroid cartilage is palpated on the ventral midline (Fig. 43-9). The skin incision is extended from the rostral aspect of the thyroid cartilage forward toward the basihyoid bone. The *sternothyroideus* muscles are separated bluntly on the ventral midline, and the incision is extended to the loose fascia between the thyroid cartilage and the basihyoid bone (Fig. 43-10). The *hyoepiglotticus* muscle is enclosed in elastic fascia (hyoepiglotticus ligament) deep to the loose fascia. The *hyoepiglotticus* muscle within its fascia is retracted to one side of the incision (Fig. 43-11), and the incision is extended through multiple layers of loose fascia until the oropharyngeal mucosa is reached. The latter is picked up with a rat’s tooth forceps and opened with curved scissors. Further exposure is obtained by splitting the basihyoid longitudinally.
with an osteotome. Malleable or Langenbeck retractors are needed to retract each side of the incision laterally and the root of the tongue rostrally.

The incision is closed using no. 0 polyglactin 910 or no. 0 poliglecaprone (Monocryl, Ethicon, Johnson and Johnson) in a simple-interrupted-continuous pattern on the oropharyngeal mucosa. A few simple-interrupted sutures are used to reapproximate the loose areolar tissue ventral to the oropharyngeal mucosa. The basihyoid (if it was split) is reapproximated using a simple size 2 steel suture. The sternohyoid muscle is reapproximated using a no. 0 polyglactin 910 or no. 0 Monocryl in a simple-continuous pattern. The subcutaneous tissue and skin are closed only over the split basihyoid bone. Complete closure is not recommended because of the clean-contaminated nature of the incision.

FUNCTIONAL DISORDERS OF THE NASOPHARYNX

Rostral Pharyngeal Collapse

Rostral pharyngeal collapse (i.e., fluttering of the rostral aspect of the soft palate) has been observed during treadmill videoendoscopy and was once thought to be a precursor to DDSP. This condition has been reproduced experimentally by bilateral transection of the tendon of the tensor veli palatini muscle.9 In this experimental model, rostral instability of the soft palate caused inspiratory obstruction, but DDSP did not occur. The rostral aspect of the soft palate billows dorsally during inspiration, since it is unable to resist nasopharyngeal pressures (Fig. 43-12). It is displaced ventrally during exhalation, so it interferes only with ventilation during inhalation.

Horses with rostral pharyngeal collapse are presented with a history of upper respiratory noise caused by billowing of the rostral soft palate. The diagnosis can be obtained only by videoendoscopic examination of nasopharyngeal function while the horse is exercising on a treadmill. The clinical significance of this condition as it relates to athletic performance is unknown, but it is unlikely to be performance limiting because of the minor obstruction observed. However, rostral soft palate instability may be associated with DDSP; therefore, evaluating the horse for DDSP is required. If billowing of the rostral aspect of the soft palate...
If significant nasopharyngeal inflammation is present, the use of local and systemic anti-inflammatory agents is indicated. The author administers 20 mL of a throat spray twice a day (composed of 250 mL of glycerin, 250 mL of 90% DMSO, 500 mL of nitrofurazone, and 50 mL of prednisolone 25 mg/mL) and a course of dexamethasone (30 mg IV or PO once a day for 3 days, followed by 20 mg IV or PO once a day for 3 days, then 10 mg IV or PO once a day for 3 days, and finally 10 mg IV or PO every other day for three treatments). In addition, the author empirically recommends a dropped or figure-eight nose band to maintain airflow into the oropharynx.

There is no proven surgical treatment, but decreasing the compliance of the rostral aspect of the soft palate is logical. The author has used laser palatoplasty, a diode laser (12 watts) with a contact fiber of 600 µm and pulse duration of 3 seconds (Fig. 43-13) to topically laser the soft palate. In addition, it seems rational to consider two other treatments, tension and thermal palatoplasty, which were designed to decrease compliance of the rostral soft palate because their authors hypothesized that this condition was a precursor to DDSP. These two treatments are both performed through an oral approach.

**Thermal Palatoplasty**

The horse is placed under general anesthesia using an intravenous agent, and a mouth gag is placed. The tongue is pulled rostrally and the head elevated to facilitate an oral view of the proximal aspect of the ventral soft palate (appropriate lighting is required). A metal instrument is used to protect the tongue during the procedure. Custom-built “irons” made of two 1-cm-diameter, 50-cm-long steel rods, with a 4- to 6-cm length welded on one end to form a T shape. Using a heated T-shaped metal instrument, the ventral surface of the soft palate (oropharynx) is cauterized, from the hard palate extending caudally to beyond the palatoglossal arch (Fig. 43-14, A and B). Cauterization obliterates the two parasagittal longitudinal folds of the soft palate (see Fig. 43-14, B), and this results in a permanent scar (see Fig. 43-14, C), which is thought to decrease the compliance of the soft palate.
**Tension Palatoplasty**

After general anesthesia induction and placement of a mouth gag, an elliptical incision is made through the oral mucosa, starting immediately caudal to the caudal edge of the hard palate. An elliptical section of approximately two thirds of the rostral soft palate mucosa and submucosa is excised (9 to 12 cm long by 1 to 2 cm wide) using long-handled forceps and curved Metzenbaum scissors (Fig. 43-15). The mucosal and submucosal edges are reapposed using 0 Vicryl or Monocryl in a simple-interrupted pattern. The procedure can be repeated in 4 weeks (a procedure termed maximum tension palatoplasty) to further increase the tension in the soft palate.

Postoperatively, horses are fed mash and wet hay for 3 to 7 days before returning to work. They are administered phenylbutazone for 3 to 5 days and a trimethoprim and sulfonamide combination for 5 to 7 days. Walking exercise is resumed after 2 days (walking and trotting only), and training can resume in 4 weeks. The degree of postoperative pain is reportedly minimal after thermal palatoplasty (2 to 3 days) compared with tension palatoplasty (up to 7 days in some cases).

Prognosis is related to the degree of collapse. A guarded prognosis should be given, since the current knowledge of this condition is limited.

**Dorsal/Lateral Nasopharyngeal Collapse**

Some horses with exercise intolerance and upper respiratory noise are observed to have (1) unilateral or bilateral ventral displacement of the roof of the nasopharynx (Fig. 43-16) or (2) axial displacement of the lateral walls of the nasopharynx, or both (Fig. 43-17). A certain degree of collapse is normal in horses during exercise. For instance, the roof of the nasopharynx does normally displace ventrally at the end of expiration during exercise. At rest, the pressure in the guttural pouches, which form the roof of the nasopharynx, is in phase with nasopharyngeal pressure, and the pressure...
in the guttural pouches is subatmospheric when no airflow is present at rest. During exercise, guttural pouch pressure does not stay in phase with nasopharyngeal pressure. Nasopharyngeal peak expiratory pressure is reached earlier than in the guttural pouch during the expiratory cycle, so peak expiratory pressure in the guttural pouch laggs behind pressure changes in the nasopharynx. Therefore, the roof of the nasopharynx normally collapses at the end of expiration, but this should not extend beyond the ventral surface of the fully abducted arytenoid cartilages. It is known from experimental studies of dysfunction of the stylopharyngeus caudalis muscle (see Fig. 43-4) results in collapse of the roof of the nasopharynx. Presumably, intraluminal collapse of the lateral walls of the nasopharynx occurs because of dysfunction of the palatopharyngeus muscles. Dysfunction of these muscles may be associated with severe inflammation or neuritis of the pharyngeal branch of the vagal or glossopharyngeal nerve. Alternatively, dorsal and lateral nasopharyngeal collapse may be the result of a sensory dysfunction that prevents appropriate reflex contraction of the intrinsic musculature of the nasopharynx. Guttural pouch distention leads to ipsilateral nasopharyngeal roof collapse. Other systemic diseases, like an HYPP episode, botulism, or equine protozoal myelitis, could be the cause. Finally, nasal obstruction may lead to more negative inhaling airway pressure, overwhelming the muscular activity of the intrinsic nasopharyngeal musculature.

In the clinical disease, collapse of the nasopharynx occurs during inhalation, causing a greater reduction in the diameter of the lumen of the nasopharynx than in the cross-sectional diameter of the rima glottidis. In the author's experience, this condition is most commonly seen in 2- and 3-year-old racehorses. Clinical signs of dynamic dorsal pharyngeal collapse include inspiratory upper respiratory noise and exercise intolerance. Diagnosis can be made by endoscopic examination during nasal occlusion (without sedation) or, more accurately, during treadmill exercise. The guttural pouches and both nasal cavities should also be examined, looking for the primary cause of this disease.

Treatment should be directed toward resolution of the primary condition (e.g., guttural pouch disease, nasal obstruction, systemic disease). In young horses, an anti-inflammatory protocol (as described under “Rostral Pharyngeal Collapse,” earlier) should be considered. Affected 2-year-old horses can be allowed to mature until their 3-year season. Some experimental treatments are under investigation, but there is no stabilizing treatment available yet.

**Dorsal Displacement of the Soft Palate**

Intermittent DDSP is a performance-limiting upper airway condition in horses that was identified in 1.3% of a population of 479 horses examined endoscopically at rest. However, the prevalence of this condition is probably higher, because palate displacement is a dynamic condition that occurs most frequently during intense exercise, making diagnosis at rest difficult. The prevalence of this condition is probably closer to 10% to 20% of 2- to 3-year-old racehorses.

The horse is an obligate nasal breather, perhaps to allow the olfactory senses to function during deglutition. The normal epiglottis is positioned dorsal to the soft palate and contacts the caudal free margin, forming a tight seal around the base of the soft palate. The pillars of the soft palate converge dorsally, forming the palatopharyngeal arch. When the soft palate displaces dorsally, the epiglottis cannot be seen in the nasopharynx and is positioned in the oropharynx (Fig. 43-18). The caudal free margin of the soft palate billows across the rima glottidis during exhalation, creating airway obstruction (see Fig. 43-18). Upper airway pressure measurements made in horses clinically affected with DDSP during treadmill exercise indicate that DDSP is an expiratory obstruction. This observation was confirmed by measuring upper airway mechanics in horses in which DDSP was induced by bilaterally blocking the pharyngeal branch of the vagus nerve. Tracheal expiratory pressure and impedance were increased, minute ventilation was reduced, and horses were more hypoxic and hypercarbic than controls.

DDSP was first reported in 1949, and since then the understanding of the pathophysiology of this disease has increased. DDSP usually interferes only with ventilation during exercise, producing upper respiratory noise. In some cases, there is a digestive disturbance that leads to feed, water, and saliva contamination, predominately of the upper airways. It is important to identify this digestive disturbance for the following reasons. Horses with DDSP are usually presented with a respiratory deficit only, which occurs during intense exercise. This presentation carries a reasonable prognosis, and treatment varies depending on the specific cause. However, DDSP with digestive deficit generally indicates a more advanced deficit of the palatineus muscle (or its innervation) or an anatomic deficit (such as cleft palate or an acquired deficit of the caudal free edge of the soft palate—i.e., staphylectomy or loss of epiglottic cartilage secondary to septic epiglottis or surgical resection) that allows feed contamination of the nasopharynx from the oropharynx. In addition, marked tracheal aspiration of feed material into the trachea (generally from laryngeal disease or its treatment) can lead to DDSP (although the pathophysiology of this association is not clear). Equine clinicians should...
carefully attempt to identify the cause if feed contamination of the upper airway is seen in association with DDSP, and they should be aware that routine treatment of intermittent DDSP may not be successful and could even worsen the condition.

**Clinical Study–Based Hypotheses of the Etiology of DDSP**

A series of mainly mechanical factors have been implicated in the etiopathogenesis of DDSP, and all are supported only by clinical association and not by experimental investigations. The condition was initially attributed to a paretic or an overly long soft palate.32 No data support the overly long soft palate hypothesis except perhaps in rare cases in foals.33 Cysts on the caudal free edge of the soft palate have been observed to interfere with the normal subepiglottic position of the soft palate. This seems to be a mechanical effect, since removing the cyst results in immediate postoperative correction of the DDSP. Other lesions that mechanically interfere with the junction of the caudal free edge of the soft palate and subepiglottic tissue are also believed to result in DDSP. They include subepiglottic or palatal granuloma (Fig. 43-19), masses, and cysts (see Fig. 44-25). The current understanding is that these masses predispose to DDSP, either by mechanically interfering with the seal between the caudal free edge of the soft palate and subepiglottic tissue or by causing irritation or pain that stimulates DDSP.

Epiglottic hypoplasia or deformation has been implicated as a cause of DDSP in horses.34,35 It was thought that inadequate length or rigidity of an epiglottis might make it unable to “hold” the soft palate in a subepiglottic position.34,35 Equine practitioners have noted that some horses affected with intermittent DDSP have what appears to be a hypoplastic or flaccid epiglottis. The author has noted that horses experience DDSP at exercise after a progression of morphologic changes prior to DDSP (as observed endoscopically during high-speed exercise). First, caudal retraction of the larynx leads to an increase in “apparent flaccidity” of the epiglottic cartilage and billowing of the soft palate, followed by DDSP. A swallow seems to reset the larynx and the subepiglottic position of the soft palate to the correct rostral position. This progression of events is repeated a few times before persistent DDSP is seen.

Therefore, a flaccid epiglottis is probably a result rather than a cause of the DDSP seen when checking the larynx position or tone of intrinsic/extrinsic musculature. Indeed, the role or importance of an abnormal epiglottis as the initiating factor in DDSP is questionable, because DDSP does not occur despite the fact that epiglottic cartilage is not present to “hold the palate down” when epiglottic retroversion is experimentally induced.36 Also, there was no statistical correlation between the epiglottic appearance of horses that exhibited DDSP during treadmill examination and those that did not displace their soft palate, suggesting that epiglottic appearance may not directly correlate with the occurrence of DDSP.30 Therefore, the author no longer believes that epiglottic augmentation35 should be used routinely to treat horses with intermittent DDSP, but a description of the technique can be found in Chapter 44 for the sake of completeness.

Other factors implicated in the pathogenesis of DDSP include caudal retraction of the tongue, caudal retraction of the larynx because of excitement, and opening of the mouth.37 If the tongue is retracted, the base of the tongue may “push” the soft palate dorsally, inducing DDSP. In this instance, a tongue-tie pulls the tongue out of the mouth and prevents this occurrence. As mentioned earlier, recent experimental investigations failed to identify a morphologic or physiologic effect from a tongue-tie.12,13,38 One report showed that DDSP was reversed in two out of six horses by using a tongue-tie.39 The presence of excessive muscle contractions leading to caudal retraction of the larynx because of a horse’s excitement or nervousness during racing or

---

**Figure 43-19.** A, Palatal granuloma in a 2-year-old Thoroughbred with dorsal displacement of the soft palate. B, Appearance of the granuloma dorsal to the palate and ventral to the epiglottic cartilage (arrows) with the soft palate replaced.
performance has been proposed as another cause of DDSP.\textsuperscript{37} This has led to sedation or to surgical transection of the strap muscles to prevent the larynx from retracting.

The clinical association of opening the mouth or swallowing during exercise and the induction of DDSP has led to the following hypothesis. Opening the mouth lets air enter the oropharynx, disturbing the stabilizing effect of the subatmospheric pressure on the ventral surface of the soft palate.\textsuperscript{1} This has led to the use of a dropped or figure-eight nose band to prevent DDSP during exercise. There is no experimental data investigating this hypothesis.

**Experimental Study-Based Hypotheses of the Etiology of DDSP**

Many studies described at the beginning of this chapter have led to the identification of intrinsic and extrinsic factors responsible for the stability of the nasopharynx at exercise. Events that interfere with the neuromuscular control of the nasopharynx, such as a deficit of the pharyngeal branch of the vagus nerve or palatine or thyrohyoid muscle function, can lead to DDSP. Deficits of the palatine muscle function also lead to feed and water contamination of the upper airway.\textsuperscript{6}

**History and Clinical Signs**

Racehorses with intermittent DDSP generally have a history of exercise intolerance and may make a gurgling or vibrating noise during exhalation.\textsuperscript{37} These horses may be described as "chooking down" or "swallowing their tongue." Concurrent with these signs is open-mouth breathing. Other horses used for show or pleasure riding may exhibit only the respiratory noise described earlier.

**Diagnosis**

The diagnosis of intermittent DDSP is based on a history of poor performance associated with respiratory noise, observation of the horse competing or racing, physical examination, and endoscopic examination of the upper airway at rest, preferably immediately after strenuous exercise or while the horse is exercising on a treadmill. A complete physical examination is important to rule out other causes of exercise intolerance, such as pulmonary disease, cardiac abnormalities, lameness, and neurologic disease.

**Treatment**

Neuromuscular pathology has been suggested as a possible etiology of DDSP.\textsuperscript{6} Dorsal displacement of the soft palate was historically referred to as soft palate paresis.\textsuperscript{35} Recently, persistent DDSP was created by bilaterally blocking the pharyngeal branch of the vagus nerve as it coursed through the guttural pouch.\textsuperscript{6} Therefore, dysfunction of the pharyngeal branch of the vagus nerve associated with inflammatory disease in the guttural pouch can interfere with palatine and palatopharyngeus muscle tone, leading to DDSP. Lending credence to this theory, horses with intermittent DDSP have an elevated prevalence of upper respiratory inflammatory diseases such as pharyngitis that may affect the function of the pharyngeal branch of the vagus nerve.\textsuperscript{6,40}

Treatment is initially directed at modifying or eliminating factors associated with DDSP occurrence. Unfit horses should be conditioned and reevaluated before surgical intervention is considered. Tack changes may be suggested to alter the horse’s head position, and a figure-eight noseband used to keep the horse from opening its mouth. The bit may be changed, and a bit that secures the tongue (such as a W bit, a spoon bit, or a "Serena song" bit) may be used. These bits are designed to restrict caudal movement of the tongue and are generally used in addition to a tongue-tie.

Tongue-tie use has been popular for many years. Initially the hypothesis was that it prevented "swallowing of the tongue" or, perhaps more medically accurate, prevented the root of the tongue from applying dorsal pressure on the ventral surface of the soft palate.\textsuperscript{27} As mentioned earlier, four recent papers looked at the efficacy of the tongue-tie.\textsuperscript{12,13,38} In one study, two out of six horses were improved with a tongue-tie, as evidenced by treadmill videoendoscopy.\textsuperscript{39} The author has observed two horses exercising on a high-speed treadmill that were normal without a tongue-tie and displaced their palate only when the tongue was tied. The three other papers failed to detect a mechanical effect (a change of nasopharyngeal diameter or upper airway patency) when the tongue-tie was used.\textsuperscript{12,13,38} A "bit-less" bridle (see www.bitlessbridle.com) was recommended as a treatment of this condition, on the basis of the belief that a bit in the mouth caused DDSP. More recently, a throat-support device that positions the larynx and basihyoid more rostrally during exercise has been shown to prevent DDSP at exercise in experimentally created DDSP\textsuperscript{41} and shows promise as a management tool in clinically affected horses (Throat Support Device; * Vet-Aire, Inc, Ithaca, New York; see www.Vet-Aire.com).

The data are insufficient to draw clear conclusions on these training aids. Using the tongue-tie, removing the tongue-tie, trying different bits, and using a figure-eight nose-band are all valid changes when the diagnosis is first made. If upper respiratory tract inflammation was diagnosed during the examination, treatment should include judicious use of systemic anti-inflammatory medication and topical anti-inflammatory agents such as glycerin, DMSO, and nitrofurazone. Medical treatment should be continued for 30 days, and subsequently the horse should be reevaluated before training is resumed or surgical intervention is considered. A recent study reported a 60% success rate when these medical treatments were used alone,\textsuperscript{82} a figure similar to the outcome seen after many surgeries!

**SURGICAL OPTIONS**

If medical treatment and tack management fail to correct soft palate displacement at exercise, many surgical options are available. The following is a description of the more commonly used techniques. Tension\textsuperscript{79} and thermal palato-
plasty,\textsuperscript{32} described previously, are recommended by some surgeons to treat soft palate displacement as well.

Of all these procedures, which should be used? No double-blind controlled studies have been performed, and experienced surgeons (e.g., H. Lewellyn, P. Hogan, T. Ahern, R. Oldridge, J. Robertson, J. Stick, G. Lane, E. Parente) often disagree on the procedure of choice for treating DDSP. The author believes that morphologic or anatomic abnormalities involving the nasopharynx or subepiglottic and epiglottic cartilage (such as bacterial or viral epiglottitis, cyst, granuloma, aryepiglottic entrapment) should be addressed medically or surgically through a nasal, oral, or laryngotomy approach. Otherwise, the best treatment is a laryngeal tie-forward combined with a partial resection of the thyrohyoid muscle or tendon.

STAPHYLECTOMY

Staphylectomy, or partial soft palate resection, originally was described as a treatment for an excessively long soft palate.\textsuperscript{32} This condition does not exist except perhaps in neonatal foals,\textsuperscript{25} so staphylectomy should be discontinued as a routine treatment of DDSP. When more than 0.75 cm of the soft palate is removed, the seal between the oropharynx and the nasopharynx can be disturbed and allow the passage of feed and fluids (water and saliva) into the nasopharynx. Staphylectomy should be reserved to resect a granuloma or cyst from the caudal free edge of the soft palate.

Preoperatively, the horse can be treated with NSAIDs and broad-spectrum antibiotics. Staphylectomy is performed with the horse under general anesthesia and positioned in dorsal recumbency with the head and neck extended and prepared for a laryngotomy.\textsuperscript{43,44} (Fig. 43-20). A 10- to 12-cm skin incision is made along midline, centered over the cricothyroid space. The sternohyoideus muscles are divided bluntly using a curved Mayo or Metzenbaum scissors. A self-retaining retractor, such as a Weitlaner or a Hobday, is placed between the separated sternohyoideus muscles, exposing the cricothyroid membrane. The cricothyroid membrane is sharply incised (along with the underlying laryngeal mucosa) with a scalpel along the midline, from the cricoid cartilage to the junction of the thyroid cartilages (see Fig. 43-20). A small blood vessel is usually also incised at the level of the caudal two thirds of the membrane. The vessel is ligated or cauterized. The self-retaining retractor is subsequently placed within the cricothyroid space. The caudal free margin of the soft palate rostral to the incision is identified. If the horse was not intubated, the soft palate may not displace, and the caudal edge of the soft palate may have to be freed from beneath the epiglottis using a pair of sponge forceps. If the horse was intubated orally, the palate will be displaced and the endotracheal tube should be retracted at this time. The mass or cyst is identified and resected using a curved Satinsky thoracic scissors. If the palate is being trimmed for DDSP, the mucosa of the caudal free margin of the soft palate is grasped with an Allis tissue forceps on the midline, and a second pair of forceps is used to grasp the mucosa 2 to 2.5 cm lateral to the midline. If desired, the caudal free margin of the soft palate is trimmed between the Allis tissue forceps, beginning laterally and ending on the midline. An Allis tissue forceps is placed on the other side of the soft palate, again approximately 2 to 2.5 cm from midline, and the caudal margin of the soft palate is trimmed from the lateral forceps toward the incision. A crescent-shaped 4- to 5-cm-long piece of mucosa that is 0.5 cm wide on the midline and tapered toward both ends should be resected.

The laryngotomy incision may be left to heal by second intent, or preferably the cricothyroid membrane is reapproxosed using no. 0 polyglactin 910 suture material in a simple-continuous pattern. Some surgeons may elect to completely close the laryngotomy incision, but this step increases morbidity unnecessarily. Postoperatively, the horse should wear a muzzle for several hours. Systemic antibiotic therapy is continued for 7 days, and anti-inflammatory medication is continued for 3 days. The laryngotomy incision should be cleaned twice daily until it is healed (approximately 3 weeks). The horse can begin training 2 to 3 weeks later. A success rate of 50% to 60% is reported for treating DDSP after this procedure.

Complications of staphylectomy are uncommon but can occur if too large a section of the soft palate is resected. These horses may be dysphagic, leading to signs of aspiration that include coughing, expulsion of feed material through the nose, and pneumonia. In addition, horses may develop permanent DDSP.
STANDARD MYECTOMY

Standard myectomy (a partial sternohyoideus and sternothyroideus, with or without omohyoideus resection) is performed to reduce caudal retraction of the larynx. Sections of the sternothyroideus and sternothyroideus muscles are removed with the horse standing as the procedure was first described. If the plan is to also remove a section of omohyoideus muscle, the procedure should be performed under general anesthesia with the horse positioned in dorsal recumbency and the head and neck extended. This is because a more extensive dissection is required when the omohyoideus muscle is resected.

The horse should be treated preoperatively with NSAIDs and broad-spectrum antibiotics. It is restrained in a set of stocks, a stanchion, or a stall doorway. Tranquilization may be necessary or useful. (Alternatively, the horse is anesthetized and placed in dorsal recumbency.) The hair is clipped from incisonal surfaces of the neck, and the area is aseptically prepared. Local anesthetic is infiltrated along the midline at the junction of the proximal third and the middle third of the neck.

A 10-cm ventral midline incision is made through the skin, continuing through the cutaneous colli muscles. The paired sternohyoideus muscles are identified. Using curved forceps, the sternohyoideus and sternothyroideus muscles are undermined. The sternothyroideus muscle is positioned caudolateral to the sternothyroideus muscle at this level of the neck. The muscles are elevated through the incision and clamped with a Rochester-Carmalt forceps at the proximal and distal extent of the incision. The muscle bellies are sharply transected between the forceps, and a 6- to 8-cm long section of muscle is removed. The muscle tissue that was removed should be inspected to ensure that sections of both sternohyoideus muscles and the smaller sternothyroid muscles were indeed removed. If the omohyoideus muscles are also removed, the dissection (under general anesthesia) must extend laterally up to the ventral border of the left and right jugular veins. More significant dead space is created, so a Penrose drain and application of a postoperative cervical bandage are indicated. The subcutaneous and skin layers are closed routinely. If a Penrose drain is used, it is placed alongside the ventral aspect of the trachea and tunneled through a stab incision distal to the surgical incision. A firm bandage is applied around the neck and may be removed along with the drain 24 hours later.

NSAIDs can be continued for 3 days, and antibiotics should be continued for 5 to 7 days. The horse is kept in a stall with daily hand-walking for 2 weeks. Training can be resumed 2 weeks after surgery, when the sutures are removed. Complications are usually related to the incision and include incisional seromas and infections. No long-term complications are notable except for the cosmetic defect associated with the lack of muscle tissue at the surgical site. Reports indicate a success rate of 58% to 71% for treating DDSP after this procedure.

MINIMALLY INVASIVE MYECTOMY

Minimally invasive myectomy (partial sternothyroidectomy or the Llewellyn procedure) is rapidly performed and has minimal morbidity. Partial sternothyroidectomy and tenectomy is performed with the horse under general anes-

PHARYNX

INDUCTION OF PALATAL FIBROSIS

This procedure is usually performed in combination with the partial sternothyroidectomy resection. It has been proposed that the compliance of the soft palate can be reduced by induction of fibrosis. This fibrosis was induced in the past by performing a staphylectomy. A laser is used to induce fibrosis on the nasopharyngeal mucosa on the caudal aspect of the soft palate. The stiffening that results is thought to increase the intrinsic strength of the caudal soft palate so that it is able to resist pressure changes during strenuous exercise.

Horses undergoing transendoscopic laser cauter of the soft palate are sedated and restrained in stocks. The endoscope is passed through the nasal passage into the nasopharynx, and a local anesthetic is applied topically. The 600-µm laser fiber is passed through the biopsy channel, and the caudal free margin of the soft palate is lased as follows. The fiber contacts the soft palate for 1 to 2 seconds at 2- to 4-mm intervals along the entire caudal free margin and extending 1.5 cm rostrally (15 watts, 600 to 800 joules) (Fig. 43-21). Routine laser safety precautions must be applied, including protective eyewear appropriate for the laser wave length and laser signs restricting entry into the operating theater to ensure safety of all personnel.

LARYNGEAL TIE-FORWARD

The recently described laryngeal tie-forward is performed with the horse anesthetized and in dorsal recumbency. The ventral cervical and intermandibular areas extending 10 cm rostrally to the basihyoid bone are prepared aseptically. A ventral skin incision is made starting 2 cm caudal to the cricoid cartilage and extending 2 cm rostral to the basihyoid bone. The sternothyroideus muscle is separated on the midline and bluntly dissected free of the dorsolateral aspect of the larynx lateral to the thyrohyoideus muscles. Using a 3.2-mm drill bit, a hole is made in the rostral aspect of the basihyoid bone, taking precautions to avoid damage to the vascular structures dorsal to the basihyoid bone (Fig. 43-22). The needle of two nonabsorbable sutures (size 2 or 5 polyblend sutures, Arthrex Inc, Naples, Fla) is placed from

=A=[100]
the ventral to the dorsal aspect of the basihyoid bone. One suture is then passed twice into the right lamina of the thyroid cartilage near the insertion of the tendon of the sternothyroid tendon (Fig. 43-23). The procedure is repeated with the other suture in the left lamina of the thyroid cartilage. A bilateral partial sternothyroidectomy is performed at this time. The sutures are tied so the rostral aspect of the thyroid cartilage is located immediately dorsal and 0.5 to 1 cm rostral to the caudal border of the basihyoid bone (Fig. 43-24). Closure is obtained by reapposing the sternohyoideus muscles with no. 0 poliglecaprone (Monocryl, Ethicon, Johnson and Johnson) in a simple-continuous pattern. To prevent postoperative seromas, the loose fascia overlying the larynx is incorporated into that closure. The subcutaneous tissues and skin are then closed in an acceptable manner. In the first clinical population \( (N = 116) \) of racehorses where the procedure was performed, an 80% to 82% success rate was obtained after surgery.49

NASOPHARYNGEAL DISORDERS OF FOALS

Choanal Atresia

Early in embryonic development, a membrane separates the oral and the nasal cavities.50 Choanal atresia, a rare upper respiratory malformation in horses,51-54 is a congenital abnormality associated with failure to resorb this bucco-

---

Figure 43-22. Intraoperative view of the laryngeal tie-forward procedure. Surgical view showing a 3.2-mm drill bit making a hole in the rostral aspect of the basihyoid bone. An Army-Navy retractor is placed dorsal to the basihyoid bone to avoid inadvertent damage to adjacent vascular structures.

Figure 43-23. Schematic showing the principle of the laryngeal tie-forward procedure. Note that the sutures are placed from the basihyoid into the lateral and caudal aspects of the lamina of the thyroid cartilage. The point where the needle is inserted to place the suture in the thyroid cartilage is immediately ventral to the tendon of the sternothyroid muscle. The suture is passed twice through the thyroid cartilage and tied with a slip knot on the ventral aspect of the basihyoid bone.

Figure 43-24. Closure of the lateral aspects of the thyroid cartilage with a simple-continuous pattern.
Nasopharyngeal Dysfunction

Nasopharyngeal dysfunction, characterized by respiratory distress, respiratory stridor, and dysphasia, can occur in foals during the first month of life. Endoscopic examination may reveal severe nasopharyngeal edema, laryngeal edema, milk pooling in the nasopharynx, and persistent DDSP.

The etiology of this obstructive syndrome is unknown. However, on the basis of information obtained from

to apply pressure that promotes clotting at the surgical site. After a few minutes, the tube is removed and each flap resected (the aforementioned forceps may be used to apply tension on the flaps as needed). Postoperatively, the animal receives a 5-day course of phenylbutazone (1 mg/lb PO bid) or a similar NSAID.

The second treatment approach is used when the choanal membrane is osseous or the condition is bilateral, and a nasal flap giving access to the caudal aspect of the nasal passage is required. The choanal membrane (bone) is resected, as well as part of the nasal septum using a nasal bone flap. The foal is anesthetized and placed in lateral recumbency, and an endotracheal tube is placed through a tracheostomy. A C-shaped incision (for unilateral lesions) or an S-shaped incision (for bilateral lesions) is made over the nasal bones starting at the level of the medial canthus of the eye and extending rostrally to approximately the middle of the nasal cavity, which is near the level of the infraorbital foramen. The periosteum is incised on the midline extending laterally to an area near the nasomaxillary suture, taking care to stay at least 1 cm axial to the infraorbital canal. A nasal bone flap is created along the line of the periosteal incision by placing an osteotome at a 45-degree angle to create a ridge for the bone flap to rest on at the end of surgery. The nasal bone flap is made in the shape of the periosteal incision. The procedure must be performed bilaterally if the atresia is bilateral. The nasal mucosa is excised, and the choanal membrane is identified and resected, along with the caudal nasal septum if necessary. The area is packed with sterile rolled gauze, which exits the nostril and is sutured to the false nostril.

If necessary to operate on a young foal, the third approach can be used. The membrane is resected through a laryngotomy after placing the endoscope through the nares to illuminate the persistent membrane. The author’s preference is to incise the membrane using endoscopic control and to place a stent in the nostril to prevent stricture. In the author’s limited experience, Nd:YAG laser dissection of the membrane has been unrewarding because profuse hemorrhage rapidly obscures the endoscopic view, preventing the application of local pressure in a small foal. The membrane is incised best using laparoscopic scissors with unipolar or bipolar cautery under endoscopic control, while the foal is under general anesthesia. A nasotracheal tube is placed through the surgically created fenestration and sutured to the false nostrils. The stents are removed 14 days postoperatively. Appropriate antibiotic therapy is used.

Because of the rarity of this condition, the prognosis is not well known, and persistence of airway obstruction is a possible complication. The heritability of this condition is unknown.
neonatal laboratory animals and human infants, nasopharyngeal dysfunction in neonatal foals may be related to immaturity of the neuromuscular reflexes and defense mechanisms that support the nasopharynx and larynx. Specifically, newborns have a smaller number of pressure and flow receptors in the upper airways than adults, and these receptors discharge at a slower rate. Some of the sensory and motor nerves that supply the larynx and nasopharynx are demyelinated at birth, and they change and mature morphologically until 12 months of age. Perhaps this immature neural circuit causes muscular dysfunction and incoordination in the nasopharynx that results in dysphasia and nasopharyngeal collapse, although this is only speculation.

A thorough physical examination, an endoscopic examination, and radiography of the thorax and pharyngeal region should be performed when evaluating a foal with nasopharyngeal dysfunction. While examining the foal, precautions should be taken to provide it with a patent airway if the examination induces respiratory distress. Appropriate blood work, including serum chemistry, complete blood count, serum IgG levels, and an arterial blood gas, should be performed.

Treatment may begin by securing a patent airway for the foal. Respiratory distress may be sufficiently severe that an emergency tracheotomy is performed immediately. If the foal has persistent DDSP, a laryngotomy followed by placement of a tracheotomy tube usually corrects this problem. Rarely, a staphylectomy may be needed to correct this problem. However, surgical intervention is not necessary in many foals. It is best to support the foal medically for 1 month to see if the problem resolves. Clearly, surveillance and prophylaxis for possible aspiration pneumonia should be strongly considered. White muscle disease should be identified and treated, because this may also cause nasopharyngeal dysfunction. If edema is present, anti-inflammatory medication may be useful in improving function. If the foal is dysphagic, enteral feeding can be performed through a nasogastric feeding tube, or parenteral feeding can be initiated.

Most often, these foals recover from nasopharyngeal dysfunction in 10 to 30 days. The nasopharyngeal edema resolves and dysphasia dissipates. Long-term survival rates and effects of this episode on future athletic performance are unknown.

Cleft Palate

Cleft palate (palatoschisis) is a rare congenital defect in foals. The cleft is caused by an interruption in embryologic closure that occurs along the midline in a rostral-to-caudal direction of the palatal folds and may, therefore, involve portions of the soft palate, or of the hard and soft palate. Defects in the lips and maxilla that frequently occur with cleft palate in people have never been reported in horses. The exact etiology of this defect is unknown, but genetics, nutrition, teratogens, and traumatic mechanical factors that could affect palatal fold closure during the 47th day of gestation are possible causes.

Clinical signs of a cleft palate include milk draining from the foal’s nose after nursing, coughing, and signs of aspiration. The cleft may be observed during an oral examination or diagnosed by digital palpation, or both. Endoscopic examination, using a pediatric endoscope, is helpful in making the definitive diagnosis and assessing the extent of the defect. A careful endoscopic examination is necessary as the field of view with a pediatric endoscope is small. A small but clinically significant cleft may be obscured by epiglottic cartilage or saliva. It is helpful to make the foal swallow a few times to ensure that the palate is intact. The margins of the soft palate will be visible, and the epiglottis will be positioned in the oropharynx. Once a cleft palate has been diagnosed, the foal should be examined for other congenital defects.

If the cleft is small (about one third of the soft palate) and tracheal aspiration is minimal, it may be better to delay surgery while closely monitoring the foal so that aspiration pneumonia does not go undetected. Weaning the foal early seems to decrease tracheal aspiration, as feed reaches the trachea less readily than milk. The advantage of delaying surgery is that a larger oropharynx facilitates surgical manipulation and more precise surgical repair. If the cleft is large or tracheal aspiration of milk is significant, treatment options should be restricted to either surgical repair of the cleft palate or euthanasia. Allowing foals to continue with the cleft palate is a poor choice, because of their resultant poor quality of life and morbidity from chronic aspiration pneumonia. Surgical repair of a cleft palate is considered a salvage procedure, and it is fraught with complications. Palatoplasty usually results in some degree of failure because of complete or partial dehiscence of the repair. Reoperation is frequently needed and often unsuccessful. Pneumonia can be a serious, even life-ending, complication despite attempts to repair the cleft, because of the initial aspiration of milk or feed material.

The prognosis is affected by the size of the defect, the length of the soft palate involved, involvement of the hard palate, and pneumonia. Repair of asymmetric defects should not be attempted, because there will not be sufficient tissue available for reconstruction. Also, similarly, if more than 20% of the soft palate tissue is missing, repair should not be attempted. Cleft palate defects that occur on the midline with minimal tissue missing have a successful prognosis of 50%. If the hard palate is involved, the chance of success, defined as an animal that can eat and grow normally, drops significantly. Little information is available on whether the respiratory function of the soft palate during strenuous exercise can be restored (i.e., there are no reports about the prognosis for athletic endeavors).

Surgical Approaches

Preoperative care includes broad-spectrum antibiotic coverage and plasma transfusion if the IgG level is inadequate. If the foal already has pneumonia and is aspirating feed material, the surgery should be postponed, systemic antibiotics continued, and the foal fed enterally through a nasogastric feeding tube or parenterally.

Surgical approaches to the palate include a transoral approach, laryngotomy, pharyngotomy, and mandibular symphysiotomy. Pharyngotomy with a split of the basihyoid bone is used to repair a cleft involving the caudal third of the soft palate (see previous description of pharyng-
gotomy under "Surgical Approaches to the Nasopharynx or Oropharynx," and Figs. 43-9 and 43-10). Mandibular symphysiotomy provides the best exposure to the hard and soft palate\(^63\) (Fig. 43-25). To perform a palatoplasty using the mandibular symphysiotomy approach, the foal is placed under anesthesia and positioned in dorsal recumbency. A tracheotomy is performed, and the endotracheal tube is placed in the trachea (see Fig. 43-25, A). Hair is clipped from the lower lip to the proximal trachea, and the skin is prepared for aseptic surgery. A skin incision is made from the hyoid to the lower lip (Fig. 43-25, B). The skin and gingiva over the mandibular symphysis are completely incised, and the mandibular symphysis is severed using a scalpel blade (in a neonate), an osteotome, or an oscillating

---

**Figure 43-25.** A and B, A ventral midline incision is made from the angle of the mandible to the lip. Before splitting the symphysis, a hole is prepared to facilitate realignment of the bones during closure. The lip has been moved orally to avoid morbidity associated with incising it. a, mylohyoideus; b, mandibular lymph nodes; c, sternohyoideus and omohyoideus muscles. C, The mandibles are spread, and the rostral oral mucosa is incised. The mylohyoideus and geniohyoideus muscles are incised near their tendinous origin. They should be cut with enough tissue left to suture them together for closure. D, The exposed ventral surface of the oral mucosa is tensed by further spreading of the mandibles. It is incised as far caudally as possible. Care is taken to avoid the sublingual salivary gland near the mandible and the lingual nerve near the tongue. E, The edges of the incision are covered with moistened sponges or towels and spread as far as possible. The nasotracheal tube is visible through the cleft. Two stay sutures are placed at the caudal corners of the cleft.

*Continued*
Figure 43-25, cont’d. F, Tensing the edges of the cleft with the stay suture, a #12 Bard-Parker blade is used to split the thickness of the tissue. The stay sutures can be held by an instrument inserted through a laryngotomy. G, A simple-continuous (or a Lembert) pattern is placed in the nasal side of the split edge in a rostral-to-caudal direction. H, A continuous horizontal mattress pattern is placed in the oral side of the split edge. Two to four widely spaced interrupted vertical mattress sutures are placed to reduce tension on the primary suture line. I, Soft tissues are apposed and a lag screw or pin with figure-eight wire is placed using the previously drilled hole. A cerclage wire around the rostral mandible just caudal to the erupted incisors augments stability.

Bone saw. It is preferable to avoid incising the lip to minimize postoperative dehiscence and discomfort. This is achieved by making a transverse incision at the base of the lip so the lip can first be moved caudally to give access to the symphysis. After splitting the symphysis, the lip is moved orally. The mandible spread achieved is slightly less after splitting the mandibular symphysis compared with splitting the lower lip, but it reduces morbidity. Surgical dissection subsequently proceeds along the right ramus of the mandible, and the attachments of the mylohyoid, geniohyoid, and genioglossus muscles are transected, exposing the buccal mucosa. The buccal mucosa is sharply incised, allowing the rami of the mandibles to be retracted (Fig. 43-25, C and D). A thin malleable retractor may be inserted through the laryngotomy incision over the base of the tongue to push the tongue out of the surgical field. Moist towels should be used to retract the mandibles.

After the cleft is repaired, the mandibles are apposed and stabilized with a single ASIF cancellous screw or a Steinmann pin supplemented by a hemi-cerclage, and the central incisors are wired together. The buccal mucosa is closed, and the geniohyoid and mylohyoid muscle layers are apposed and reattached. The lip is reconstructed by closing the gingiva, muscle layer, and skin (Fig. 43-25, I). The laryngotomy is left open, and the skin incision from the mandibular symphysis to the laryngotomy incision is closed with sutures interrupted by 2-cm gaps for drainage.

A successful two-step repair of a cleft palate through a purely transoral approach was reported in a 4-week old colt. Because the instruments were too short, the procedure had to be stopped 4 cm short of the caudal rim, and it was completed 4 weeks later, after the initial repair had healed. In this procedure, a special mouth speculum with a long, narrow extension into the mouth was used to elevate
the tongue out of the surgical field. Illumination of the surgical field was provided by a pediatric endoscope, which was introduced through one of the nasal passages.64

SOFT PALATE REPAIR
Graffe was the first surgeon to attempt surgical closure of cleft palate in humans in 1816, but he reported poor results.65 Little progress was made until Langenbeck (1961) described a new technique to close a palatal cleft using two bridge flaps. The technique was further modified in 1967, when Kriens suggested that the main surgical problem with palate repair was caused by the misoriented muscles in the soft palate, which, instead of building a velopharyngeal sphincter mechanism, have an insertion in the hard palate66 (Fig. 43-26). To solve this problem, the faulty origin of the palatopharyngeus and levator veli palatini muscles was resected from the hard palate and subsequently included in the cleft repair, which resulted in a more anatomically correct reconstruction of the soft palate. The interposition of the palatal muscles between the oral and nasal mucosa led to good functional results in humans.67

The soft palate is identified, and the cleft is evaluated. A surgical light is directed into the incision. If a pharyngotomy was used for access, the videocendoscope is placed orally. If a pharyngotomy is performed through one of the nasal passages.64 After dividing the oral and nasal mucosa on both sides of the cleft, the muscular layer was exposed. Through two palatal incisions, the hard palate is inspected at its caudal end. The misoriented muscles are detached from their anatomically abnormal insertion on the hard palate and redirected into the correct orientation (see Fig. 43-26). In a first layer, the nasal mucosa is repaired using 2-0 monofilament nylon sutures in an interrupted everting pattern. Subsequently, the previously dissected muscle ends are sutured in the midline to build up a new velar sphincter. Finally, the oral mucosal layer is closed in a pattern identical to that used for the nasal mucosa.

A minimally invasive technique to reconstruct a cleft palate can be achieved with a technique similar to that used for human cleft palate closure.64 After dividing the oral and nasal mucosa on both sides of the cleft, the muscular layer was exposed. Through two palatal incisions, the hard palate is inspected at its caudal end. The misoriented muscles are detached from their anatomically abnormal insertion on the hard palate and redirected into the correct orientation (see Fig. 43-26). In a first layer, the nasal mucosa is repaired using 2-0 monofilament nylon sutures in an interrupted everting pattern. Subsequently, the previously dissected muscle ends are sutured in the midline to build up a new velar sphincter. Finally, the oral mucosal layer is closed in a pattern identical to that used for the nasal mucosa.

Because it is difficult to repair the caudal end of the soft palate, a combined transoral and laryngotomy approach is an alternative to provide good apposition and reconstruction of the cleft palate.68 To provide better access to the caudal aspect of the soft palate, the thyroid cartilage may be split sagittally (Fig. 43-27). The surgical repair of the soft palate is identical to the one previously described. At the end of the procedure, the thyroid cartilage is sutured with three single interrupted sutures of no. 2 monofilament nylon.68 The incision of the cricothyroid membrane is closed in a simple-continuous pattern with 2-0 polyglactin 910 suture material. The subcutaneous tissues and skin are left to heal by second intention.

HARD PALATE REPAIR
Repair of hard palate defects is performed using mucoperiosteal flaps. Hemorrhage can be controlled by injecting small volumes of 2% lidocaine with epinephrine along the incision lines in the hard palate. A mucoperiosteal incision is made parallel to the maxilla from the junction of the hard and soft palate to a few centimeters beyond the defect. The entire width of the mucoperiosteum is elevated to the edge of the defect using a periosteal elevator. Care is taken to preserve the palatine artery, which can be seen as it emerges
from the palatine foramina at the caudalateral aspect of the hard palate at the level of the second molar. As the flap is elevated, the palatine artery stretches, and the entire flap is moved axially. The rostral (rostral hard palate) and caudal (junction of the hard and soft palates) attachments of the mucoperiosteal flap are preserved. The nasal mucosa of the flap is closed in a simple-continuous pattern using absorbable suture material, and the mucoperiosteal flaps are sutured together with horizontal mattress sutures. The defects along the lateral aspect of each mucoperiosteal flap heal by second intention.

**Postoperative Care**

If only the soft palate was repaired, the foal is allowed to nurse. If the soft palate defect was extensive or the hard palate was repaired, or both, the foal should be fed enterally through a nasogastric feeding tube or parenterally for 7 to 10 days. Broad-spectrum antibiotics should be continued for 5 days unless the foal has pneumonia, in which case antibiotics are continued until the pneumonia resolves. The repair may be assessed by careful oral examination (by looking in the mouth, not by digital palpation), but endoscopic examination is not recommended during the early postoperative period.

Dehiscence is the most likely and most severe complication. Generally, dehiscence is apparent within the first 7 to 14 days and is evidenced by nasal reflux of food and coughing. Other complications include pneumonia, osteomyelitis of the mandible, salivary fistulas, and incisional infections.61

Larynx
John A. Stick

ANATOMY
The larynx forms the communicating channel between the pharynx and the trachea, and it functions during breathing, vocalization, and deglutition. It is composed of cartilage and muscle and is lined with a mucous membrane composed of stratified squamous and pseudostratified columnar ciliated epithelium.2

The cricoid, thyroid, and epiglottic cartilages are unpaired, whereas the arytenoid cartilages are paired. The cricoid cartilage is shaped like a signet ring and is positioned rostral to the first tracheal ring and connected to the trachea by the cricoatracheal membrane.1 The thyroid cartilage is the largest of the laryngeal cartilages and is situated just rostral to the cricoid cartilage. The arytenoid cartilages are positioned on either side of the cricoid cartilage and are connected to it by the cricoarytenoid articulations. The articulation is a diarthrodial joint that allows the arytenoid cartilage to rotate dorso-laterally during abduction, and axially during adduction.1 Each arytenoid cartilage has a corniculate process that forms part of the dorsal border of the rima glottidis, a cuneate process, and a muscular process that serves as origin for the cricoarytenoideus dorsalis muscle. The epiglottis rests on the dorsal surface of the body of the thyroid cartilage and is held there by the thyroepiglottic ligaments. It consists of elastic cartilage and is shaped like an oblanceolate leaf.1

Contraction of the intrinsic laryngeal muscles produces changes in caliber of the rima glottidis by abducting and adducting the corniculate processes of the arytenoid cartilages and the vocal folds and therefore altering airway resistance. These muscles include the paired cricoarytenoideus dorsalis, thyroarytenoideus (ventricularis and vocalis muscles), and cricothyroideus and cricoarytenoideus lateralis muscles, plus the unpaired transverse arytenoideus muscle.2 The cricoarytenoideus dorsalis is the principal abductor muscle that widens the laryngeal aperture by abducting the corniculate process of the arytenoid cartilage and tending the vocal folds.2,3 Contraction of the arytenoid transversus muscle also provides arytenoid abduction by drawing the dorsomedial margins of the arytenoid cartilages together.1 The thyroarytenoideus, arytenoideus transversus, and cricoarytenoideus lateralis muscles adduct the corniculate processes of the arytenoid cartilages, narrowing the rima glottidis and protecting the lower airway during swallowing.1,3 The cricothyroideus muscle tenses the vocal folds during vocalization but receives efferent motor innervation from the external branch of the superior laryngeal nerve, a branch of the vagus nerve, whereas all other intrinsic laryngeal muscles receive motor innervation from the recurrent laryngeal branch of the vagus nerve.1,2

The extrinsic laryngeal muscles of the larynx include the thyrohyoideus, hyoepiglotticus, and sternothyroideus muscles1 and are involved in stabilization of the larynx and pharynx during exercise. The mucosa of the larynx is closely adhered to the cartilages and contains many different types of afferent receptors. The mucous membrane covering the epiglottic cartilage reflects off the lateral border of the epiglottis and blends with the mucous membrane covering the corniculate processes of the arytenoid cartilages, forming the aryepiglottic folds.1 The mucous membrane covers the vocal ligament, forms the vocal folds, and lines the lateral ventricles, forming the laryngeal saccules. These saccules are 2.5 cm deep with a capacity of 5 to 6 mL.1 They extend between the medial surface of the thyroid cartilage and the ventricularis and vocalis muscles. The laryngeal mucosa contains mechanoreceptors specialized in their sensory modalities for the detection of different stimuli, including transmural pressure changes, airflow, temperature, and laryngeal motion.4 These receptors receive afferent neural supply from the internal branch of the superior laryngeal nerve, a branch of the vagus nerve.4 This rich sensory supply is the main source of many respiratory reflexes that influence upper airway patency and breathing patterns.5,6

The larynx receives arterial blood supply from the caudal laryngeal and branches of the ascending pharyngeal arteries. Venous drainage is provided by the caudal laryngeal and ascending pharyngeal veins, which flow to the external jugular vein via the thyroid vein. The lymph chains that serve the laryngeal area include the retropharyngeal and the cranial and deep cervical lymph centers.1

ARYTENOID CARTILAGES
The paired arytenoids are the most dynamic of the laryngeal cartilages (along with the epiglottis). The articulations with the cricoid cartilage allow complete closure of the glottis during swallowing (adduction) and maximal opening (abduction) during exercise (Fig. 44-1). These dynamics of the arytenoids make them vulnerable to injury, inflammation, and dysfunction and also dictate the impact their dysfunction has on performance. Therefore, the necessity for treatment becomes obvious for athletes.

The body or laminar portion of the arytenoids, like the thyroid and cricoid cartilages, consists of hyaline cartilage, which is subject to ossification with age or trauma. However, the apex of the arytenoids, which curves upward and backward, forms a pitcher-shaped lip (from which the cartilages derive their name) that is readily observed on endoscopic examination.

Laryngeal Hemiplegia (Recurrent Laryngeal Neuropathy)

Etiology and Incidence
Horses can develop unilateral or bilateral paralysis of the arytenoids.6,9 Unilateral left-sided laryngeal paralysis is most commonly encountered (Fig. 44-2) and results from progressive loss of large myelinated nerve fibers in the left recurrent laryngeal nerve, hence the term recurrent laryngeal neuropathy has been suggested as a name for this disease.5 In
almost all of these horses, no precise cause is evident and the term idiopathic laryngeal hemiplegia is applied, although a genetic predisposition is most likely. Progressive neurogenic atrophy of the intrinsic laryngeal musculature, most importantly the cricoarytenoideus dorsalis muscle, results in progressive loss of both abductor and adductor arytenoid function. Laryngeal hemiplegia occurs in horses from a few months to 10 years of age and older, with large-breed horses more commonly affected than small-breed horses or ponies. Incidence is highest in young horses and commonly discovered in Thoroughbred yearlings that are examined at sale time, before they have started any type of training, or in 2- and 3-year-olds that are racing or are in race training. Although the incidence of complete idiopathic laryngeal hemiplegia was 2.75% in a study of Thoroughbred yearling sales, overall incidence in the entire yearling population is likely to be higher. In fact, in a recent study of 427 Thoroughbred sale yearlings, 64% had asynchronous/asymmetrical arytenoid cartilage movements and 25% (107) had laryngeal asymmetry that was significantly associated with decreased racing performance.

In a normal horse during sustained exercise, the larynx dilates fully to maximize airflow. Complete arytenoid cartilage abduction is sustained, despite the increased negative inspiratory pressure, throughout the respiratory cycle as exercise intensity increases. In the horse with laryngeal hemiplegia, arytenoid abduction on the affected side cannot be achieved and there is a progressive collapse of the arytenoid cartilage and vocal cord into the airway as negative inspiratory pressures increase (Fig. 44-3). This produces airflow limitations that result in hypoxemia, hypercarbia, and metabolic acidosis, which develop more rapidly than in a normal horse with the same workload, causing early fatigue and poor performance.

A specific etiology can be identified in some horses with acquired laryngeal paralysis, unilateral or bilateral. The recurrent laryngeal nerve can be damaged as a result of perivascular injection intended for the jugular vein, guttural pouch mycosis, trauma from injuries or surgical procedures of the neck, strangles abscessation of the head and neck, and impingement by neoplasms of the neck or chest. Organophosphate toxicity, plant poisoning, hepatic encephalopathy, lead toxicity, and central nervous system diseases have also been shown to cause laryngeal paralysis. In a recent study of 375 cases of laryngeal hemiplegia in a mixed-breed population of horses, 94% (351) were idiopathic in origin. However, in non-idiopathic cases (6%), over half were bilaterally affected.

Diagnosis
A presumptive diagnosis of laryngeal hemiplegia is made on the basis of history and the findings of a physical examination. Horses with left recurrent laryngeal neuropathy have a history of upper airway obstruction during exercise that includes an abnormal inspiratory respiratory noise, characterized as a whistle or a roar, and exercise intolerance. The noise is the result of air turbulence created as air passes over the affected vocal cord, and over the ventricle, which acts as a resonator.
Physical examination should include palpation of the neck and larynx, because horses with complete paralysis of the left arytenoid cartilage will have palpable atrophy of the cricoarytenoideus dorsalis muscle.\textsuperscript{16} The larynx should also be palpated for congenital malformation and evidence of arytenoid chondritis.\textsuperscript{21,24} If there was previous laryngeal surgery and a laryngotomy was performed, there is usually a linear scar on the ventral aspect of the larynx, over the cricothyroid membrane, which can be palpated. Laryngoplasty and laryngotomy scars can be identified visually after clipping the hair over the incisions.

A definitive diagnosis is made on endoscopic examination when there is a loss of abductor function on the affected side of the larynx (see Fig. 44-2). Because various descriptions of the loss of abductor function (hemiplegia, complete and incomplete paralysis, and paraplegia) lead to confusion, a four-point laryngeal function grading system has been adopted to more precisely describe arytenoid cartilage activity as assessed on endoscopic examination in resting horses\textsuperscript{25} (see Table 41-1). Arytenoid abduction can be stimulated by inducing swallowing or by nasal occlusion in the resting horse. If there is any question as to whether a horse shows complete or incomplete abduction, an exercise test can be carried out and endoscopy performed immediately after cessation of exercise. A more reliable alternative is to perform videoendoscopy during exercise on a treadmill, observing for dynamic collapse of the arytenoid cartilage and the associated vocal cord (see Chapter 41). The video image can be recorded and reexamined in slow motion later.\textsuperscript{26}

In the absence of access to a high-speed treadmill, endoscopic examination of the upper airway of horses standing at rest is still commonly performed not only for the diagnosis of suspected upper respiratory obstructive disorders but also as routine surveillance for horses in training and for prepurchase examinations. This has strengthened the recognition that variations in arytenoid cartilage movements of the equine larynx are common. The laryngeal movements in a horse unaffected by clinically significant recurrent laryngeal neuropathy would have complete synchronous and symmetrical abduction maintained during nasal occlusion during a resting endoscopic examination. However, it is recognized that asynchronous and asymmetric arytenoid cartilage movements are common and may or may not indicate failure of arytenoid function during athletic exercise.\textsuperscript{27} The clinical significance of these variations in cartilage movement has been controversial. However, it is generally recognized that increasing degrees of laryngeal movement dysfunction result in poor athletic performance and, therefore, it is an undesirable characteristic found during the endoscopic examination of the equine athlete. Furthermore, it is recognized that horses with laryngeal neuropathy, even after treatment with prosthetic laryngoplasty, often have a guarded prognosis for full restoration of athletic performance.\textsuperscript{27}

Therefore, interpretation and significance of altered laryngeal cartilage movements during the endoscopic examination falls to the veterinarian, who must make an educated prediction of how these altered movements will affect the horse’s performance. To do this, the veterinarian must not only determine how severely affected the larynx is but also answer the question, “Will these altered laryngeal movements progress to complete laryngeal paralysis?” The 1982 literature contained a study in which 168 horses were examined over a period of several years, and there was no apparent progression from asynchronous abductor function to complete paralysis.\textsuperscript{28} This led the investigators to conclude that such movement was normal. Subsequently, the four-point classification system for arytenoid cartilage movements was developed to predict present and future arytenoid dysfunction based on resting endoscopic evaluation. Although clinical and experimental studies suggested that the laryngeal neuropathy may have been progressive, no factual evidence was available in the literature.

However, a recent study showed that recurrent laryngeal neuropathy is progressive.\textsuperscript{29} The long-term histories and clinical findings of 351 horses suffering from recurrent laryngeal neuropathy were examined for evidence of progression of laryngeal asymmetry. Fifty-two out of 351 cases (15%) had evidence of progression of the degree of laryngeal dysfunction over a median period of 12 months. The implication is that today’s findings do not apply to the future and, therefore, periodic reexamination is indicated, and prognosis for athletic prowess can change as a direct result.

This study also indicated that many of the adult horses had an acute onset of exercise intolerance and inspiratory stertor. If this disease is thought of as progressive, it is assumed to be slow and insidious. However, the clinical signs may, in fact, be caused by a slow progression that finally reaches a threshold, at which point cranial arytenoideus dorsalis muscle fatigue occurs, permitting complete arytenoid collapse during exercise. This manifestation could result in a history of acute onset.

Last, variation in the endoscopic appearance of arytenoid cartilage movements has been reported to be common.\textsuperscript{17} It has been suggested that this variation, when it occurs days or even hours later, is often because of intra-assessor variation or laryngeal muscular fatigue from multiple reexaminations. However, differences in clinical and endoscopic findings between veterinarians who perform prepurchase and postpurchase examinations, perhaps just weeks apart, may in some cases simply reflect clinical progression of recurrent laryngeal neuropathy rather than intra-assessor variation.

Treatment

Treatment of laryngeal hemiplegia includes laryngoplasty, ventriculectomy (sacculectomy), ventriculocordectomy, occasionally arytenoidectomy, and neuromuscular-pedicle grafting.\textsuperscript{26} However, selection of a particular surgery to treat laryngeal hemiplegia is based on the presenting complaint, use of the horse, and class of arytenoid cartilage movement. When considering this decision, the surgeon should recognize that some horses with laryngeal hemiplegia are able to work to capacity despite the upper airway obstruction. The decision to operate on the upper airway should be based on clear evidence that it is needed, because complications are too frequent to operate on a horse simply because the owners or trainers want to fix all blemishes on their athlete. Some sport horses tolerate upper airway embarrassment quite well when speed is not the issue. Therefore, each of the surgical techniques used to treat laryngeal hemiplegia should target a particular problem.
It is well recognized that horses that work at speed for longer than one-half mile could be greatly affected by obstructions of the upper airway. At these speeds and distances, reduction in the laryngeal aperture by 50% increases the work of breathing 16-fold. Therefore, intervention in the form of a laryngoplasty to eliminate this obstruction is warranted. However, there is evidence that combining ventriculocordectomy or ventriculocordectomy with this procedure neither prolongs the life of the surgery nor improves upper airway flow mechanics.

In the show and performance horse, the respiratory noise caused by laryngeal hemiplegia is an important clinical problem because being "unsound of wind" may result in penalization. Therefore, the primary goal of surgery in the performance and show horse is to eliminate the respiratory noise caused by laryngeal hemiplegia rather than to reduce the airway obstruction. In a recent study, it was shown that bilateral ventriculocordectomy effectively reduces inspiratory noise in laryngeal hemiplegia–affected horses by 90 days after surgery. Conversely, it was shown that laser vocal cordectomy does not effectively reduce the noise associated with laryngeal hemiplegia by 120 days after surgery. Both of these techniques modestly improve airway flow mechanics, but bilateral ventriculocordectomy is the treatment of choice for noise reduction. Clinical experience suggests that bilateral standing ventriculotomy has a very similar result in draft breeds, decreasing airway noise while improving air flow mechanics. Although laryngoplasty reduces respiratory noise in horses with laryngeal hemiplegia, ventriculocordectomy is more efficacious in reducing airway noise in the normal hearing range. A further advantage of ventriculocordectomy over laryngoplasty is that postoperative complications after laryngoplasty are more prevalent and severe and include dysphagia, aspiration pneumonia, chronic cough, wound infection, and prosthetic failure. Furthermore, sound production should not be used as an indicator of surgical success in horses when restoration of upper airway flow mechanics is the primary goal of surgery.

There is a poor correlation between the sound indices and degree of airway obstruction as measured by inspiratory pressure. In fact, it has been shown that there was a strong positive correlation in the degree of arytenoid abduction and sound indices. It would have been predicted that a greater abduction would be correlated with less respiratory noise, but the opposite was true.

Occasionally, partial arytenoidectomy is chosen to treat laryngeal hemiplegia when there is a congenital malformation of the cartilages or the laryngoplasty technique has failed because of fractures in the cartilage. Likewise, neuro-muscular pedicle grafting is reserved for young horses where return to athletic function is not expected before 4 months after surgery, particularly when laryngeal cartilage movements are still present but are expected to affect performance (grade 3).

Before laryngeal surgery, horses are fasted for 8 to 12 hours. Preoperative and perioperative nonsteroidal anti-inflammatory medication (phenylbutazone) and broad-spectrum antibiotics are indicated for these surgeries for a period of 5 days. The anesthetist should be aware that some horses with a longstanding unilateral arytenoid paralysis can be difficult to intubate with a standard-size tube, and a smaller-diameter tube should be available. The larynography procedure is performed with the horse in right lateral recumbency. In unique situations, the horse may be first placed in dorsal recumbency to allow for visual and digital inspection of the arytenoid cartilages through a laryngoscope. This approach might be taken when endoscopic observations suggest the presence of subtle arytenoid chondritis or when there has been previous laryngeal surgery. If the cartilage is diseased or has lost flexibility and cannot be pushed into an abducted position, the surgeon may elect to proceed directly to an arytenoidectomy rather than perform a laryngoplasty.

LARYNGOPLASTY

Laryngoplasty is the placement of a prosthesis (suture) between the cricoid and arytenoid cartilages (Fig. 44-4). The goal of the laryngoplasty technique (tieback) is to achieve some degree of permanent abduction of the affected arytenoid cartilage. The perfect result for an individual horse is the arytenoid position that achieves a balance between giving the horse enough of a laryngeal opening to perform but not so much abduction as to allow aspiration of saliva, food, and water during swallowing. The art of performing this surgery is finding that balance.

With the affected side uppermost, the head and neck are extended for best surgical exposure. A videoendoscope can be secured in position at this time to allow intraoperative viewing of the larynx by the surgeon. The surgical site is routinely prepared and draped, and a 10- to 12-cm skin incision is made ventral and parallel to the linguofacial vein, extending caudally from a point 4 cm cranial to the ramus of the mandible. This position is the center of the incision over the caudal aspect of the larynx. With Metzenbaum scissors, the linguofacial vein is separated from the omohyoid muscle along the length of the incision. To maximize exposure, it may be necessary in some horses to ligate and divide the vascular pedicle from the linguofacial vein that enters the omohyoid muscle. The lateral and dorsal aspects of the larynx are exposed using blunt digital separation of the loose connective tissue, avoiding dissection beyond the dorsal midline of the larynx. A malleable retractor is used in the dorsal portion of the incision to expose the larynx. The muscular process lies beneath the cranial portion of the cricopharyngeus muscle and is exposed by sharply separating the cricopharyngeus and thyropharyngeus muscles along their aponeurosis. The esophagus, thyroid gland, laryngeal and thyroid vessels, and ventral branch of the 1st cervical and cranial laryngeal nerves should be avoided during site preparation and suture placement.

Two sutures of silicone-treated, braided polyester (no. 5 Ticon, Sherwood-Davis & Geck, St. Louis, Mo) or similar large-caliber nonabsorbable suture materials are used for the prosthesis. The large, swaged-on, reverse-cutting needle on the Ticon is used, or the suture can be placed through the eye of a no. 3 Martin uterine reverse-cutting needle and the ends tagged with a small hemostat. (This type of needle is less likely to break off in the laryngeal cartilages than a cutting needle, and it pierces cartilage more easily than a tapered point needle.) Using the left index finger as a guide, the needle is walked off the caudal aspect of the cricoid cartilage just lateral to the dorsal midline until the point slips under the cartilage. (There is a notch in the cricoid at
this site, but its location can be quite variable.) The needle is advanced in a cranial direction, avoiding the lumen of the larynx. Then the needle is rotated to penetrate the cricoid cartilage 2 to 3 cm cranial to its caudal border and 1 cm lateral to the dorsal ridge (Fig. 44-5, A). The left index finger is used to ascertain the site of penetration. The needle is drawn through the cartilage and out of the incision. The needle is cut off and the suture ends are tagged with a small hemostat. A large hemostat is passed under the cranial aspect of the cricopharyngeus muscle, and the points are brought out at the site of penetration of the cranial end of the prosthetic suture. This end is then grasped and drawn under the muscle and brought out of the incision. The lead ends of the prosthetic suture are then placed on a smaller (no. 6 Martin uterine reverse-cutting) needle, which will be used for placing the suture through the muscular process. The needle is positioned on the caudomedial aspect of the muscular process and passed in a craniolateral direction through the muscular process, drawing the prosthetic suture through the muscular process (see Fig. 44-5, B). The needle is removed and tension is placed on the cranial and caudal portion of the suture to remove any slack and to be certain that it is tight against the larynx. A second suture is placed in a similar position but 1 cm more caudal in the muscular process. The trailing ends of the prosthetic sutures are then drawn under the cricopharyngeus muscle with a hemostat and the sutures are tied (see Fig. 44-4). Care must be taken to ensure that each trailing suture end is matched to its leading end, and that each suture is placed before one is tied (to avoid cutting the tied suture).

The thyropharyngeus and cricopharyngeus muscles are reapproximated with single-interrupted sutures, and the fascia adjacent to the linguofacial vein is apposed to the omohyoides muscle with simple-interrupted sutures of 2-0 synthetic nonabsorbable suture material. The skin is closed with staples or 2-0 nonabsorbable monofilament suture material.

Variations of the laryngoplasty technique include placement of one prosthetic suture; the use of a crochet hook, rather than a needle, to pull the leading edge of the prosthesis through the muscular process; and the use of tension and crimping devices to adjust and secure the prosthetic

---

**Figure 44-4.** Schematic illustration of the correct placement of the laryngoplasty suture and its effects on arytenoid position. **A,** Lateral view of single prosthetic suture in place and tied. **B,** Dorsal view of the larynx, showing configuration of the laryngoplasty suture. **C,** Endoscopic image of a grade 4 laryngeal hemiplegia before laryngoplasty. **D,** Endoscopic appearance of the larynx after laryngoplasty with the left arytenoid cartilage in moderate abduction. **E,** Endoscopic image of an overabduction of the left arytenoid cartilage because of excessive tension of the suture.
Regardless of the technique used, the following principles should be observed:

- Tissue trauma associated with the initial blunt dissection over the larynx should be minimized to prevent damage to adjacent structures (particularly nerves), to reduce the possibility of postoperative dysphagia.
- The prosthetic suture should be seated securely in the cricoid cartilage and the muscular process to minimize cartilage failure.
- Placement of the suture dorsally in the cricoid cartilage, almost on the midline, is important for achieving adequate abduction. Placement of the suture too far laterally results in inadequate abduction.
- The suture must not penetrate the lumen of the larynx. (Placement of the suture in the cricoid cartilage is most likely when the lumen can be penetrated. Therefore, the endotracheal tube should be moved [approximately 4 cm] back and forth before the sutures are tied.)

Following laryngoplasty, stall rest is recommended for 30 days. Hand-walking is allowed for exercise. During the 2nd postoperative week, the swelling in the laryngoplasty incision area subsides. During the 5th and 6th postoperative weeks (30 to 45 days after surgery), the horse is exercised lightly or turned out in a small paddock or round pen. After this, training is resumed. The owner should be advised to feed hay from the ground and that the horse may develop a chronic cough associated with eating.

Complications
Intraoperative complications include bleeding from deep in the surgical site, needle breakage, and prosthetic suture “cut-through” of either the cricoid cartilage or muscular process. Significant hemorrhage can arise from laryngeal vessels that are inadvertently punctured as the needle is passed through the cricoid cartilage. Temporary packing with sponges slows bleeding and allows the placement of the prosthetic suture through the muscular process. The bleeding usually stops when the suture is tightened and tied. Therefore, the surgery should be hastened to accomplish tying of the suture as soon as possible. If the needle breaks, reasonable attempts should be made to retrieve the broken portion, but if it is securely embedded in cartilage or buried in the adjacent soft tissues and has not penetrated the lumen of the larynx, it is not likely to cause a problem. However, it will be clearly visible with radiography of the horse’s head or neck.

During the operation, when the prosthetic suture is tightened, having the suture pull through either of the cartilages is a serious problem. The suture must be replaced, avoiding the damaged portion of the cartilage and using less tension. In this instance, a second suture is always used to secure the arytenoid cartilage in an abducted position.

After surgery, large seromas may develop at the laryngoplasty site, and an endoscopic examination may show nasopharyngeal compression on the affected side. If the horse is eating well and remains afebrile (temperature less than 101° F), and if the swollen area is relatively pain free, warm compresses and anti-inflammatory drugs may be used to reduce the size of the seroma. If the horse develops a mild fever, systemic antibiotic treatment is warranted. Drainage of the laryngoplasty incision is indicated if medical treatment fails to resolve the swelling, but rarely does the prosthetic suture become infected. If the suture does become infected, chronic drainage of purulent material may occur for months. Antimicrobial therapy usually resolves the problem, and suture removal is rarely necessary and should be delayed for 4 months, since early removal may result in failure of arytenoid abduction.

Following laryngoplasty, many horses experience some degree of coughing and dysphagia. Initially, pain is associated with swallowing, and the horse may be reluctant to swallow. In the first few days after surgery, saliva, water, and food material may enter the trachea when the horse eats and drinks. This usually resolves within 7 to 10 days. In many cases, the cough persists, particularly when the horse eats. The cough is most likely the result of continued...
aspiration of saliva, water, or food material into the trachea. The cause for this pharyngeal dysfunction resulting in aspiration may be neurologic in origin or related to over-abduction of the arytenoid cartilage.

Chronic aspiration of material causes the chronic cough, and in some horses, repeated episodes of lung infection when they resume training. The diagnosis of aspiration can be made endoscopically by viewing food material in the trachea. Removal of the laryngoplasty suture may resolve the aspiration problem and even the chronic cough in some horses. Time may allow this problem to resolve in others.

Suture pull-out or failure of laryngoplasty seems more likely to occur in yearlings or 2-year-old horses, although experimentally there is no significant effect of age on the in vitro cartilage retention of the prosthesis. In that study, it was also shown that the muscular process is the part of the laryngoplasty fixation that is most likely to fail during progressive tensile loading. It was suggested that partial muscular process cartilage failure is the likely cause of post-operative "relaxation" of the suture, with some loss of abduction. This is a well-recognized phenomenon that occurs during the first 30 days after surgery. One retrospective clinical study revealed a much higher rate of successful outcome after prosthetic laryngoplasty in horses that were 2 years old or younger than in horses 3 years old or older. It therefore appears that there is no reason to exclude young horses (younger than 2 years) from laryngoplasty treatment, and that they are at no greater risk for laryngoplasty failure than older horses.

The reported success rates for laryngoplasty are variable because of the criteria that are used to measure success, the intended use of the horse, and patient selection. Although reported success rates have ranged from 5% to 90%, it is realistic to expect that 50% to 70% of racehorses treated with a laryngoplasty will have improved racing performance after surgery. The outcome is likely to be more successful in horses that are not intended to race after surgery.

In a retrospective performance analysis after prosthetic laryngoplasty, the degree of arytenoid abduction achieved did not necessarily correlate to a successful surgical outcome. Likewise, noise production should not be used as a measure of airway obstruction. For the surgery to be successful in racehorses, it appears that the arytenoid cartilage must be positioned at least just beyond an intermediate position and at somewhat less than maximal abduction. However, laryngoplasty should be viewed as a salvage procedure in racehorses, because even the horse with near maximal abduction of the arytenoid cartilage will have some airflow limitations at racing speeds.

Reoperation for failed laryngoplasty
During the surgical approach in a horse with a previous laryngoplasty incision, care must be taken not to penetrate the linguofacial vein during the dissection between the vein and the omohyoideus muscle. If the reoperation is within 10 days of the original surgery, a seroma will be encountered in the dead space created at the first surgery, and the local dissection required to expose the dorsal aspect of the cricoid cartilage usually creates a good deal of hemorrhage. In the horse that has a mature surgical area, dense scar tissue makes it difficult to expose the cricoid cartilage and the muscular process of the arytenoid cartilage. Breaking down this scar tissue digitally and with scissors can produce bleeding that will fill the surgical field. Temporary pressure from sponges packed into the incision helps to reduce hemorrhage. Intraoperative suction is necessary in these cases. Usually the object of reoperation is to remove the original laryngoplasty suture and replace it with another suture (or sutures) that pulls the arytenoid cartilage into a more abducted position. If a surgery report describing the original surgery is not available, the surgeon should be aware that there may be more than one prosthetic suture. Although the suture is buried in scar tissue, the knot can usually be found caudal to the muscular process. The suture is cut and removed entirely. The scar tissue along the lateral and caudal surfaces of the muscular process must be incised with scissors to mobilize the arytenoid cartilage. This is accomplished using the points of Metzenbaum scissors with digital guidance. A laryngoplasty suture is then placed and tied as tightly as possible.

Having a videoendoscope in place or having an assistant view the larynx with a fiberoptic endoscope allows the assessment of the position of the arytenoid cartilage after the prosthetic suture is tied (Fig. 44-6). It is important to know if the arytenoid cartilage is pulled into a more abducted position. If the cartilage is elevated away from the endotracheal tube, then it is likely that the goal of improving abduction has been achieved. If not, it is likely that the re-operation attempt will fail. With this intraoperative knowledge, the surgeon can decide whether to place another suture to try and achieve greater abduction or whether to proceed with an arytenoidectomy.

Prosthetic suture removal to correct aspiration
If over-abduction after laryngoplasty produces aspiration that necessitates reoperation, the original sutures can be removed. Another suture can be placed that fixes the arytenoid cartilage in a less abducted position after suture removal if the reoperation is performed within 2 weeks of the initial surgery. If the surgical site is mature (greater than 120 days) at the time of reoperation, simple removal of the sutures, without placing another suture, may be all that is necessary. If dissection around the muscular process during

*References 16, 26, 38, 39, 42, 43.
suture removal is minimized, scar tissue around the muscular process usually holds the arytenoid in moderate abduction.

**Special Considerations**

A number of conditions that appear similar to but are separate entities from idiopathic left-sided laryngeal hemiplegia affect the prognosis for return to athletic activity and deserve discussion. They include vocal fold collapse, bilateral laryngeal hemiplegia, rostral displacement of the palatopharyngeal arch, and right-sided laryngeal hemiplegia.

**Vocal Fold Collapse**

Vocal fold collapse is a condition observed on videoendoscopy during high-speed exercise. It occasionally occurs in horses with grade 3 laryngeal movements (see Table 41-1). Rarely, it is observed in some horses after laryngoplasty when a concurrent ventriculectomy has not been performed. Clinical signs and history are similar to those of laryngeal hemiplegia. Diagnosis is confirmed on slow-motion playback of an exercising videoendoscopic examination (Fig. 44-7). Treatment for this condition is bilateral ventriculocordectomy (described later).

**Bilateral Laryngeal Paralysis**

Bilateral laryngeal paralysis has been associated with organophosphate toxicity and with central nervous system diseases such as equine protozoal myeloencephalitis (EPM). Horses with bilateral arytenoid dysfunction usually show severe exercise intolerance with a minimal amount of exercise or stress. Some are in severe distress and make a loud inspiratory noise even at rest. Horses can die of respiratory collapse if a tracheostomy is not performed as an emergency procedure.

On endoscopic examination, there is reduced movement of both arytenoid cartilages. One arytenoid may be more severely affected than the other. Both guttural pouches should be examined endoscopically and, if the horse shows signs of ataxia, a cerebrospinal fluid tap should be performed for EPM testing.

Horses with bilateral laryngeal paralysis that is associated with a diagnosis of EPM can show improved laryngeal function after medical treatment for EPM. In horses that are in danger of asphyxiation, a temporary tracheostomy should be performed (see Chapter 46). In nonresponsive cases, a unilateral laryngoplasty and sacculectomy can be performed on the most severely affected side to salvage the horse for nonperformance activities, but aspiration can be severe because adductor function on the contralateral side may be compromised. Therefore, some estimate of adductor function should be made before unilateral laryngoplasty is undertaken. Bilateral laryngoplasty is not recommended and permanent tracheostomy should be considered.

**Rostral Displacement of the Palatopharyngeal Arch**

The term *rostral displacement of the palatopharyngeal arch* is used to describe a condition that is part of a complex of congenital pharyngeal and laryngeal abnormalities*45-48 (Fig. 44-8).* The caudal margin of the ostium intrapharyngeum is displaced rostral to the corniculate processes of the arytenoid cartilages. It is commonly seen in conjunction with thyroid cartilage abnormalities and an absence of the cricopharyngeus muscles. The laminae of the thyroid cartilages are abnormally shaped and do not articulate normally with the cricoid cartilage. Often, the malformed laminae of the thyroid cartilages limit the normal range of movement of the arytenoid cartilages. Additionally, there can be a variety of intrinsic laryngeal muscle abnormalities. A developmental abnormality of the 4th branchial arch has been proposed as the cause of the anatomic abnormalities of the thyroid cartilage and the affected laryngeal muscles, which can be unilateral or bilateral. *Cricopharyngeal-laryngeal dysplasia* is a more inclusive term that has been proposed to better describe this syndrome.48 Endoscopically, these horses can appear to have right laryngeal hemiplegia.

**Figure 44-7.** Videoendoscopic image (freeze-frame) of the larynx of a horse during exercise, demonstrating vocal fold collapse.

**Figure 44-8.** Videoendoscopic image of the larynx showing rostral displacement of the palatopharyngeal arch. The palatopharyngeal tissue is covering the apical portions of the corniculate processes, and both arytenoid cartilages show very limited abduction.
The effects of this syndrome are variable, depending on the degree of deformity present. Horses with a severe deformity show signs of respiratory obstruction and dysphagia at rest, whereas less severe deformities produce signs of upper airway obstruction only during exercise. Surgical treatment of this condition is usually unrewarding, but right arytenoidectomy can be considered.

**Right-Sided Laryngeal Hemiplegia**

Right-sided laryngeal hemiplegia is rare in horses, and an etiology should be sought, because the idiopathic form of laryngeal hemiplegia does not usually affect the right side. If none of the aforementioned causes can be detected, the surgeon should suspect congenital malformation of the laryngeal cartilages in young horses. Palpation of the muscular process of the arytenoid cartilage is an important part of the physical examination. Additionally, endoscopically these horses appear as if the corniculate process of the arytenoid cartilage on the right side is much smaller than on the contralateral side. In a series of horses treated for right-sided laryngeal hemiplegia, 7 of 11 Thoroughbreds had congenital malformation of the laryngeal cartilages. This makes the rate of laryngoplasty failure in this group of horses very high, and partial arytenoidectomy may be selected as a treatment. Although spontaneous recovery from right-sided laryngeal hemiplegia has been reported, it would not be expected to be found in the young yearling to 2-year-old Thoroughbred. A poor prognosis should be given to the owner, and some consideration should be given to performing a neuromuscular pedicle graft. However, the author's personal experience is that right-sided laryngeal hemiplegic horses have a very guarded prognosis for return to athletic activity.

**VENTRICULECTOMY (SACULECTOMY)**

Ventriculectomy (unilateral or bilateral) refers to the removal of the mucosal lining of the laryngeal ventricle located caudal to the vocal fold. It is usually performed to eliminate noise and can have some beneficial effects on performance. Because it does not produce abduction of the arytenoid cartilage, ventriculectomy is not recommended as a sole procedure for racing horses affected with laryngeal hemiplegia. However, it reduces soft tissue collapse during exercise and can be quite successful if performed on certain show horses. Because the complication rates of laryngoplasty (e.g., failure, anesthetic problems, coughing) approach 30% in draft horses, the author prefers to perform a bilateral ventriculectomy in the standing horse.

The horse is placed in the stocks and sedated with loading doses of detomidine (4 mg IV) and butorphanol (10 mg IV). After starting a detomidine drip (14 mg added to 250 mL of saline) to effect (approximately 2 drops per second for 15 minutes, 1 drop per second for 15 minutes, and so on, as the effect is highly variable), the horse’s head is elevated and the laryngotomy site is prepared. Local anesthetic is injected underneath the skin in the area of the laryngotomy approach (see Chapter 43). After the final preparation, a 10-cm incision is made on the ventral midline, centered over the junction of the horizontal and vertical rami of the mandible. The paired sternothyrohyoideus muscles are separated on the midline and the characteristic V in the thyroid cartilages is palpated. Laryngotomy is performed with a #10 scalpel blade. A burr is introduced into the ventricle to its depth and twisted, engaging the mucosa in the projections on the burr (Fig. 44-9, A and B). Occasionally, the ventricle is so large that it is necessary for the operator to press on the laminar portion of the arytenoid cartilage to enable the burr to engage the mucosa of these large saccules at their apex. The burr is then withdrawn slowly from the ventricle, everting the attached saccule. Swallowing usually occurs during this procedure and helps evert the saccule. A large hemostat is placed across the everted saccule proximal to the head of the burr (see Fig. 44-9, C), and with traction on the clamp, a second clamp is placed behind it. With digital pressure on the opening of the ventricle, the entire saccule is everted and then excised with Metzenbaum scissors (see Fig. 44-9, D). The same procedure is repeated on the opposite ventricle, which is allowed to heal along with the laryngotomy incision by second intention. The author now performs this procedure as an outpatient surgery.

**Postoperative management**

It is important that the horses receive loading doses of antibiotics any time the respiratory tract is invaded. Anti-inflammatory therapy is an important component of mini-

---

**Figure 44-9.** Schematic illustration of the ventriculectomy technique with the horse in dorsal recumbency. **A,** The "roaring" burr is placed into the laryngeal ventricle and rotated so that the head of the burr engages the mucosa of the laryngeal saccule. **B,** Once the saccule is firmly engaged, it is everted into the lumen of the larynx by steadily pulling on the burr. **C,** A large hemostat is placed across the saccule immediately adjacent to the vocal fold, and the burr is removed. **D,** The saccule is completely excised using Metzenbaum scissors adjacent to the hemostat.
Endotracheal tube can be removed if necessary to allow and neck extended. A laryngotomy is performed. The lining of the laryngeal ventricle as described earlier, as well as the surgery site heals. Therefore, it leaves a smooth surface over the ventral half of the rima glottidis. This is repeated on the other side. Preoperative and postoperative care is the same as that given for ventriculotectomy via laryngotomy.

**Complications**

Inflammation and infection of the open laryngotomy incision rarely cause a problem that cannot be resolved by establishing good drainage followed by applying a topical antimicrobial ointment. A clostridial infection at the laryngotomy site, however, can be catastrophic or even fatal. Within a 24-hour period after surgery, a clostridial infection can produce tremendous swelling of the head and neck that results in a massive tissue slough. The use of perioperative penicillin may avoid such an infection, and if it does occur, early recognition and prompt treatment with intravenous penicillin is critical.

Rarely, excessive granulation tissue forms in the ventricles after sacculectomy. This problem usually resolves with time and the application of anti-inflammatory sprays.

**Special Considerations**

Attempts to develop a technique for laser ventriculocordectomy in standing horses have not been successful. When a neodymium:yttrium aluminum garnet (Nd:YAG) laser was used in noncontact fashion via a nasal approach, or in contact fashion via an oral approach, viable mucosa of the ventricle remained after surgery, sometimes resulting in a mucocele. Additionally, although laser vocal cordectomy alone is used clinically, a recent study showed that laser vocal cordectomy does not effectively reduce the noise associated with laryngeal hemiplegia by 120 days after surgery.

Therefore, refinements in surgical technique are required before laser ventriculocordectomy can be used with confidence to obviate noise production in horses affected with laryngeal hemiplegia.

**Neruomuscular Pedicle Graft**

Young horses affected by laryngeal hemiplegia and horses with grade 3 laryngeal movements are good candidates for laryngeal reinnervation. The technique involves implantation of a nerve–muscle pedicle (NMP) graft into the cricoarytenoideus dorsalis (CAD) muscle. The 1st cervical nerve and omohyoideus muscle are used to make the NMP graft because of their proximity to the larynx. Additionally, the 1st cervical nerve is used because it depolarizes during inspiration and therefore causes abduction of the CAD muscle after reinnervation.

The patient is prepared as if for laryngoplasty, because the surgical approach is very similar. Antimicrobial and anti-inflammatory medications are instituted as for other laryngeal surgeries. Surgical instruments should include small thumb forceps, a spay hook, and a Weitlaner self-retaining retractors in addition to the instruments used for laryngeal surgery.
The horse is placed in right lateral recumbency under general anesthesia, and the head and neck are positioned for an approach for laryngoplasty. A 12-cm linear incision is made along the ventral border of the linguofacial vein that is carefully separated from the omohyoides muscle. The 1st cervical nerve lies just under a branch of the linguofacial vein that is positioned midway between the rostral and caudal aspects of the incision. The ventral branch of the 1st cervical nerve emerges through the alar foramen of the atlas, and it descends over the cricopharyngeal muscle caudal to the larynx before dividing and entering the omohyoides muscle. This nerve is commonly encountered during dissection for laryngoplasty and can be traced from the atlas to the omohyoides muscle. The main body of the 1st cervical nerve is identified, and ventral retraction of the omohyoides muscle is achieved with Allis tissue forceps. Insertions of the 1st cervical nerve can be found in the dorsal aspect of the muscle belly (see Fig. 44-10, B). Meticulous dissection is necessary to expose several branches of the 1st cervical nerve as they enter the omohyoides muscle. A middle branch of the 1st cervical nerve often divides into smaller branches and can be traced to a point of muscle entry, allowing creation of the muscle pedicles. The main branch of the 1st cervical nerve is gently retracted using a spay hook and is freed from its fascial attachments on the caudal aspect of the larynx. When harvesting the muscle pedicles, sterile mepivacaine hydrochloride is used to bathe the area so that muscles do not contract during harvesting.

Figure 44-10. Schematic illustration of the neuromuscular pedicle graft technique. A, The origin and insertion of the 1st cervical nerve into the omohyoides muscle is shown. (This nerve and muscle serve as the neuromuscular pedicle graft donors for treatment of laryngeal hemiplegia.) B, The 1st cervical nerve and future pedicle grafts of the omohyoides muscle, which has been retracted with Allis tissue forceps. C, The muscular process of the arytenoid cartilage and the exposed cricoarytenoideus dorsalis muscle, and small scissors separating the CAD muscle fibers to create pockets for placement of the muscle pedicle graft. D, The nerve muscle pedicle graft implanted into the CAD muscle.
implanted into the CAD muscle. The NMPs are created with fine scissors and are about 3 mm square.

The larynx is then rotated laterally by traction on the wing of the thyroid cartilage. The cricopharyngeus and thyropharyngeus muscles are separated along their aponoeurosis. The CAD muscle is bluntly exposed and inspected for donor site access. Then blunt separation of the cricopharyngeus muscle over the area just caudal to the muscular process exposes the CAD muscle. The window over the CAD muscle is maintained using a Weitlaner retractor. By separation of CAD muscle fibers, pockets are created and the pedicles are placed into the CAD muscle (see Fig. 44-10, C). Each muscle pedicle or nerve branch is sutured into a pocket using 4-0 polydioxanone (see Fig. 44-10, D). Closure of the incision is routine.

Horses are confined to a stall for 2 to 3 weeks after surgery until sutures are removed and inflammation has subsided. Perioperative antibiotic therapy and anti-inflammatory medications are continued for 3 to 4 days after surgery. After stall confinement, the horse receives paddock turnout for 12 weeks. At this stage (16 weeks after surgery), the horse is put into training. This time frame is based on information from studies on dogs, people, and horses, which indicates that the earliest time to see clinical evidence of reinnervation is around 12 weeks after surgery. When the horses are returned to exercise, episodes of fast exercise should be introduced as early and as frequently as possible. Because the omohyoid muscle is an accessory muscle of respiration, considerable respiratory effort must be undertaken to activate the 1st cervical nerve. After 6 weeks of training, trainers and owners are requested to present the horse for endoscopic assessment of the larynx. At rest, the left arytenoid cartilage most commonly looks exactly as it did before surgery. This is because the 1st cervical nerve is inactive at rest; thus, there is no depolarization of the nerve and no CAD muscle contraction. Two diagnostic reflexes have been developed to stimulate contraction of the omohyoid muscle and the newly innervated CAD muscle. The first involves stretching the horse's head and neck upward as high as possible while closely observing the larynx through the endoscope. If reinnervation has occurred, there is often a spontaneous flicker or single abduction of the left arytenoid cartilage. The second reflex involves pulling back rapidly with a finger or thumb on the commissure of the horse's lips. Again, a sudden abduction of the left arytenoid cartilage occurs if reinnervation has been successful. This reflex can be stimulated from the left or right side of the head.

An abductor movement of the left arytenoid cartilage indicates there has been reinnervation of the CAD muscle. Once this has been identified, the recommendation to the trainer is to continue training toward a return to racing. If there is no evidence of movement at the first revisit, the horse is turned out again for another 8 weeks, receives 6 weeks of training, and is reexamined. Horses can take up to 12 months to show evidence of successful reinnervation. Clinical experience suggests that if there is no arytenoid abduction as a result of reinnervation 9 months after surgery, there is only a small chance of improvement from that point. Reinnervation probably occurs in nearly all patients by 4 to 5 months.

The best evidence of successful reinnervation in an individual horse is derived from a treadmill endoscopic or upper airway flow mechanics study. In treadmill studies, the authors have found that those horses with movement of the left arytenoid cartilage visible at rest after NMP graft surgery maintained arytenoid abduction during vigorous exercise. If movement in the affected arytenoid could not be demonstrated in the standing horse, a dynamic collapse occurred during exercise.

Complications

Complications associated with laryngeal reinnervation are few when compared with prosthetic laryngoplasty. The most frequent complication is seroma formation 3 to 5 days after surgery. The large potential dead space that exists after the nerve graft procedure lends itself to the formation of a seroma. In the author's opinion, many of the seromas that form are caused by leaking lymphatic vessels that are inadvertently cut during surgery. Large lymph vessels travel along the lateral border of the omohyoid muscle and can be transected during the surgical approach. Disruption of the parotid salivary gland has the potential to produce large volumes of fluid continually for a number of days after surgery. Some of these seromas have resolved without intervention. Treatment of other seromas and sialoceles has involved open drainage and daily lavage. The horses have been placed on procaine penicillin therapy until the open tract continues draining. Some sinus tracts have become infected, and these have been treated with antibiotics selected from culture and sensitivity results. Because of the ventral position of the incision, once opened, the seroma and sialoceles drain easily and require minimal nursing care apart from daily lavage and attention to the skin around the incision. Horses that have suffered a postoperative incisional infection have gone on to have successful reinnervation; thus, it would seem that this complication does not necessarily compromise success of the NMP graft.

Prognosis

From experimental and clinical work, it is clear that reinnervation of the CAD muscle following an NMP graft varies from 6 to 12 months depending on the amount of CAD muscle atrophy. Therefore, horses with grade 3 laryngeal movements will respond sooner (in 4 to 6 months) than those that have grade 4 movements (complete paralysis). Because of the length of this time period, horses that are best suited for the transplantation technique are those whose immediate return to performance is not necessary. Horses that have had previous laryngoplasty for the treatment of laryngeal hemiplegia are not candidates for this surgery because of disruption of the 1st cervical nerve during that surgery. To date, over 140 horses have received NMP grafts for idiopathic laryngeal hemiplegia. Following race records in these Thoroughbreds, 60% have shown improved performance, whereas 80% have been considered a successful reinnervation. NMP grafting has allowed horses to compete successfully, and laryngeal function improves with time. Current success rate is on a parity to that of prosthetic laryngoplasty. For young horses who have never been raced and horses of high value because of their breeding potential, the NMP graft can be offered as a viable treatment for
laryngeal hemiplegia. If the result of NMP grafting is unsatisfactory, a laryngoplasty may still be performed.

**Arytenoid Chondritis**

Arytenoid chondritis is a progressive inflammatory process of the laminar portion of the arytenoid cartilage and results in a space-occupying mass within the larynx that produces respiratory noise and exercise intolerance. Because the history and endoscopic appearance of arytenoid chondritis in the standing horse is similar to that of laryngeal hemiplegia, it should always be considered in the differential diagnosis. Careful endoscopic examination is sometimes necessary to detect the hallmark sign of chondritis: a small sinus tract or granulation tissue that protrudes into the airway from the affected arytenoid (Fig. 44-11). Additionally, the corniculate cartilage is usually distorted and frequently causes mild rostral displacement of the palatopharyngeal arch (Fig. 44-12). Occasionally, palpation of the larynx for thickening around the muscular process is the only diagnostic finding.

In the acute form, horses may be presented in respiratory distress from laryngeal edema. These horses are usually treated with antimicrobials and anti-inflammatories, but occasionally they need a tracheotomy to resolve the acute condition. Medical treatment will resolve the emergency and the condition may not return. In fact, some horses remain with chronic arytenoid chondritis and perform quite well if the abnormal arytenoid cartilage does not result in residual laryngeal obstruction. However, if there is mechanical obstruction to abduction or the laminar portion of the arytenoid cartilage is thickened sufficiently when in the chronic form, surgical removal of the affected arytenoid cartilage is usually necessary. This condition is most often unilateral and therefore treated with unilateral arytenoidectomy.

**ARYTENOIDECTOMY**

Preparation of the patient should include broad-spectrum antimicrobial therapy and anti-inflammatory medication. The skin should be clipped and prepared for a laryngotomy approach (see Chapter 43) as should the mid-neck region in preparation for placement of a tracheostomy tube. If the horse has bilateral arytenoid chondritis or is dyspneic, the tube can be placed before induction of general anesthesia using local anesthetic under sedation. The author prefers this approach because often the placement of an endotracheal tube through a chondritic larynx is difficult or impossible.

Two methods of arytenoidectomy have been described: subtotal, in which the muscular process and rim of the corniculate process are left intact, and partial, in which only the muscular process is left intact (Fig. 44-13). The merits of subtotal and partial arytenoidectomy have been evaluated subjectively on the basis of the assessment of performance and postoperative complications in a series of retrospective studies. However, in a quantitative evaluation in 1990, it was demonstrated that subtotal arytenoidectomy failed to improve upper airway function in horses exercising on a high-speed treadmill with surgically induced left laryngeal hemiplegia. The effect of partial arytenoidectomy on upper airway function was evaluated by tidal breathing flow-volume analysis, measurement of upper airway impedance, and videoflouroscopic examination of the larynx in strenuously exercising horses with surgically induced left
laryngeal hemiplegia in 1994. This study showed that partial arytenoidectomy improved upper airway function in exercising horses with surgically induced left laryngeal hemiplegia and was superior to subtotal arytenoidectomy as a treatment for both failed laryngoplasty and arytenoid chondropathy.

The authors recommend combining a partial arytenoidectomy with a ventriculocordectomy and closing the entire incision in such a way that no redundant or loose tissue is left in the airway and all excised mucosal edges are apposed. In the author’s experience, any redundant tissue left in the airway creates turbulence and noise and may interfere with airway function. This tissue should be removed at 30 days after surgery via laser ablation before cicatrix formation and mineralization make it impossible. Tidal breathing flow-volume loop analysis shows that partial arytenoidectomy does not completely restore the upper airway to normal, but that the procedure is a viable treatment option for arytenoid cartilage malfunction in the horse. A detailed description of the technique for partial arytenoidectomy follows.

**PARTIAL ARYTENOIDECTOMY**

Horses are placed in dorsal recumbency under general anesthesia with an endotracheal tube placed through a tracheotomy incision (Fig. 44-14). After an approach through a ventral laryngotomy incision, granulomatous masses are often observed on the affected arytenoid cartilage (Fig. 44-15). Self-retaining retractors are used to maintain exposure and allow easy access to the lumen of the larynx. The corniculate cartilage is removed en bloc with its mucosa (Fig. 44-16, A). The arytenoid cartilage is exposed by scalpel incision of the overlying mucosa (see Fig. 44-16, B). The incision, which extends from the dorsal midline to the vocal process, is made along the caudal border of the laminar portion of the arytenoid cartilage and continued cranially along its ventral border. The mucosa is elevated from the underlying cartilage with a periosteal elevator and reflected cranially and caudally to expose the full medial surface of the arytenoid cartilage. The laminar portion of the arytenoid cartilage is then freed from its deep muscular attachments using a periosteal elevator and Mayo scissors. The remaining arytenoid cartilage is subsequently severed from its muscular process, transected at its articulation with the thyroid cartilage, and removed (see Fig. 44-16, C). A ventriculocordectomy is then performed, excess mucosa is excised, and all combined incisions are closed in a simple continuous suture pattern (see Fig. 44-16, D). During closure, the surgeon should take care to smooth the airway as much as possible by removing all redundant tissue. The laryngotomy is left unsutured because of the possibility of laryngeal edema and subsequent airway obstruction.

Antimicrobial agents such as penicillin and gentamicin, as well as anti-inflammatory drugs such as phenylbutazone, are administered before surgery and continued for at least 3 days after surgery. A tracheostomy tube should be removed and cleaned twice daily and used until there is endoscopic evidence that the edema in the laryngeal region has subsided. Postoperative endoscopic evaluations should reveal a hemilarynx devoid of vocal folds, ventricle, and corniculate cartilage (Fig. 44-17). Airway patency may also be assessed by plugging the endotracheal tube and listening for respiratory stridor. Horses are reintroduced to food 24 hours after surgery. At that time, wet hay only should be fed until the horses are able to swallow without coughing; then dry feedstuffs can be reintroduced. Horses are stall-rested for 4 to 6 weeks prior to complete healing, which usually occurs within 8 to 10 weeks.

**Complications**

Dyspnea and dysphagia are the most important complications. Dyspnea frequently occurs as the result of edema or the development of bleeding under the closed mucosa of the larynx. Therefore, the tracheostomy tube should be left in place until airway patency is confirmed. Antimicrobial and anti-inflammatory medications are continued until dyspnea is resolved, and then the tracheostomy tube is removed. Dysphagia may take longer to resolve. Coughing during eating is not uncommon and may continue for some months. Occasionally, large amounts of food and water may be regurgitated through the nose after this procedure. Aspiration is another complication that may occur, and it too may improve with time. Owners are encouraged to feed...
the animal on the ground, and pasture feeding may be beneficial.

**Granulomas**

Occasionally, particularly in Thoroughbred and Standardbred racehorses, a mass projecting from the medial surface of the corniculate process of the arytenoid is seen on endoscopic examination. These lesions are commonly referred to as chondromas; however, histologic examination of the excised tissue invariably reveals granulation tissue. An ulcerated mucosal defect is often seen on the medial surface of the opposing arytenoid where the granulation tissue rubs during laryngeal adduction. However, in a recent survey of 3312 Thoroughbred sale yearlings, the incidence of arytenoid mucosal ulceration was encountered in 21, and only a small percentage progressed to granulomas or chondromas. Ventriclectomy with focal curettage or laser ablation of these lesions has been advocated for some patients to avoid arytenoidectomy.

Transendoscopic laser excision of this granulation tissue without removal of cartilage may be a desirable method of treatment, particularly if the underlying arytenoid cartilage appears grossly normal or is only mildly thickened, and if the arytenoid cartilage has a normal or only mildly affected range of motion. Excision of the granulation tissue does not alter any preexisting underlying cartilage abnormalities, but it is carried out in an attempt to allow the mucosal defect to epithelialize and to prevent contact injury to the opposing arytenoid. This technique may be temporarily successful when combined with antibiotic and anti-inflammatory therapy in some performance horses and many sedentary patients. However, when dealing with an equine athlete, arytenoidectomy is usually required eventually.

---

**Figure 44-16.** Schematic illustration of partial arytenoidectomy technique. **A,** The corniculate cartilage is separated from the arytenoid cartilage with Metzenbaum scissors and removed. (The arytenoid cartilage is outlined by the dotted line.) **B,** Beginning at the ventral border of the junction of the corniculate and arytenoid cartilages, an incision is made through the mucosa along the ventral border of the arytenoid cartilage (heavy dark line). The incision is carried dorsally along the caudal border of the laminar portion of the arytenoid. **C,** The mucosa is elevated from the arytenoid cartilage using a periosteal elevator, which exposes the laminar portion of this cartilage. The cartilage is then freed from its deep attachments in a similar fashion. After transection of the muscular process with heavy scissors or a scalpel, the arytenoid cartilage is disarticulated from the thyroid cartilage and removed. Then the ventricle and vocal fold are removed. **D,** The mucosa is completely apposed using a simple continuous or interrupted sutures of 2-0 polydioxanone, taking care to remove any redundant tissue during closure.
The horse is sedated and the lesion and surrounding tissue are transendoscopically topically anesthetized. Using an Nd:YAG laser, a 2.2-mm-outer-diameter laser fiber with a chisel probe attached or an 800-µm sculpted fiber is introduced through the endoscope biopsy channel. A diode laser with a sculpted fiber can also be used. When using the chisel probe, the beveled surface is oriented parallel to the medial mucosal surface of the arytenoid. Beginning at the perimeter of the mass, a dissection plane is established between the granulation tissue and the underlying cartilage. The mass is completely freed up except for small remaining tags of attachment, and it is retrieved with 600-mm-long bronchoesophagoscopic grasping forceps. Any remaining small tags of loose tissue are subsequently débrided with the laser and removed with the forceps. Usually, a crater defect has been created with smooth mucosal margins that are firmly attached to underlying cartilage.

Exercise is restricted until the defect heals. Systemic nonsteroidal anti-inflammatory medication and a pharyngeal spray containing anti-inflammatory and antimicrobial medications may be useful in reducing inflammation.

**EPIGLOTTIS**

The epiglottis is an isosceles triangle-shaped structure with the tip projecting rostrally. It forms the floor of the entrance to the larynx. During normal breathing, the soft palate is positioned ventral to the epiglottis, with the free edge of the palate interfacing with the epiglottic base. The epiglottis is covered dorsally by a tightly adherent mucous membrane and ventrally by a loosely attached, somewhat redundant mucosa. The loosely folded ventral mucosa allows unrestricted dorsal and caudal movement of the epiglottis during swallowing. Endoscopically, the normal epiglottis is broad at the base, it narrows at the tip, and it has a dorsally convex surface that projects slightly above and parallel to the soft palate. The margins have distinct serrations. The normal vascular pattern seen on the dorsal surface consists of a main vessel on either side that courses from the base toward the tip, parallel to and in from the margin approximately 8 to 10 mm (see Fig. 44-1). From these two major vessels, small perpendicular branches are seen coursing toward the epiglottic margin.

**Epiglottic Entrapment**

The aryepiglottic folds are thickened bands of mucous membrane that attach along the entire free edge of the epiglottis, blending in with the tightly adherent dorsal epiglottic mucosa and the mucosa covering the corniculate process of the arytenoid cartilage. Ventral to the epiglottis, the mucosa is more loosely attached and compresses in accordion fashion when the horse is breathing normally with the epiglottis in a resting horizontal position. Epiglottic entrapment occurs when this loose mucous membrane located on the lingual epiglottic surface becomes abnormally positioned above the dorsal epiglottic surface. Epiglottic entrapment is a common cause of abnormal respiratory noise and exercise intolerance, particularly in Thoroughbred and Standardbred racehorses. Other, much less frequent complaints are coughing and nasal exudate. Occasionally, epiglottic entrapment is an incidental endoscopic finding.

**Diagnosis**

On endoscopic examination, the general shape of the epiglottis is still visible, positioned above the soft palate (Fig. 44-18). However, because the epiglottis is covered with a fold of mucosa, the distinct serrated margins of the epiglottis and the dorsal epiglottic vascular pattern are obscured. The entrapping membranes may occasionally be intermittently relieved by swallowing, but in most cases they are persistent (Fig. 44-19). On the basis of subjective endoscopic observations, the entrapping membranes may be classified as being thin or thick, narrow (less than half the length of the epiglottis) or wide (greater than half the length of the epiglottis), and ulcerated or nonulcerated (Fig. 44-20). Mucosal ulceration can vary from minimal to extensive, with variable amounts of exposed granulation tissue and pale fibrous connective tissue proliferation around the
perimeter of the ulcer (Fig. 44-21). Most epiglottic entrapments (97%) are persistent, most (98%) are thick, most (97%) are wide, and 45% are ulcerated.67

Horses with epiglottic entrapment may also suffer from varying degrees of epiglottic hypoplasia/flaccidity. On endoscopic examination, approximately 31% to 36% of horses with entrapment appear to have epiglottic hypoplasia.67,71 Lateral laryngeal radiography is used to obtain accurate thyroepiglottic length and information about epiglottic thickness and contour. In one study of 9 Thoroughbreds with epiglottic entrapment, the thyroepiglottic length was 6.59 ± 0.33 cm,75 and in another study of 35 Thoroughbreds it was 7.28 ± 0.67 cm.74 Both measurements were significantly smaller than the thyroepiglottic length found in normal Thoroughbreds without entrapment, which in two studies was 8.76 ± 0.38 cm and 8.56 ± 0.29 cm.1,74 The thyroepiglottic length in 44 Standardbreds with entrapment was 7.21 ± 0.62 cm, which was also significantly smaller than the thyroepiglottic length of 8.74 ± 0.38 cm found in normal Standardbreds.74 Among all Standardbred and Thoroughbred horses with epiglottic entrapment, those that also had endoscopically apparent epiglottic hypoplasia had significantly smaller thyroepiglottic lengths than horses with entrapment that appeared endoscopically normal.74

Treatment

Surgical correction of epiglottic entrapment has been described using transendoscopic contact Nd:YAG or diode laser axial division,67,73 transnasal or transoral axial division using a curved bistoury,68-71 transendoscopic electrosurgical axial division,72 or surgical excision through a laryngotomy or a pharyngotomy.66,69,71

At one time, conventional side-to-side excision of the aryepiglottic folds performed through a laryngotomy was recommended66; however, dorsal displacement of the soft palate was a common sequela to this technique.72 Currently, tissue-sparing techniques that preserve aryepiglottic fold mucosa and minimize scarring are preferred, in part because of the variable extent of underlying epiglottic hypoplasia found in many horses with epiglottic entrapment. Therefore, axial midline division of the aryepiglottic fold that allows the entrapping membranes to retract and heal in a normal ventral epiglottic position without removing any tissue is currently the technique of choice in most horses. The membranes can be divided with an Nd:YAG, a holmium:YAG, or a diode laser; a curved bistoury; or electrocautery, producing essentially the same effect.

With the laser, surgery can be safely performed transendoscopically on an outpatient basis with the horse standing sedated and the entrapping membranes topically anes-
thetized. Using the Nd:YAG laser as an example, a 600-µm sculpted fiber can be used to incise the membranes from caudal to rostral in contact fashion using approximately 12 W of power. Alternatively, a contact chisel probe attached to a 2.2-mm-outer-diameter fiber can be used to divide the membranes from rostral to caudal with 15 W of power. Using these two techniques, the re-entrapment rate in a series of over 500 cases was approximately 4%, and approximately 10% to 15% of horses experienced dorsal displacement of the soft palate.

Using a curved bistoury introduced either transnasally in the standing horse or transorally in the anesthetized horse (Fig. 44-22), the entrapping membranes can be incised on the midline from caudal to rostral. The reported re-entrapment rate ranges from 5% to 15%.68-71 However, serious complications after transnasal axial division using a curved bistoury on conscious horses includes division of the soft palate and lacerations of the epiglottis or pharynx. Therefore, this technique is not recommended. Inadvertent incision of the soft palate can be avoided by performing the hook technique through the mouth with the horse anesthetized. The re-entrapment rate after transoral hook correction is approximately 10%, and approximately 10% of horses experienced dorsal displacement of the soft palate.69-71 Transendoscopic electrosurgical division has the highest complication rate of the axial division techniques (in a series of five horses, it resulted in a 40% re-entrapment rate), and it has fallen into disuse.

Special Considerations
Excessively thickened, ulcerated, or fibrotic-appearing entrapping membranes are seen in approximately 5% of horses with epiglottic entrapment, and usually this condition is combined with severe epiglottic hypoplasia (Fig. 44-23). Horses with this endoscopic appearance are generally poor candidates for correction by axial division. Surgical excision of the central one third of these bulky membranes is recommended and can be performed through a laryngotomy, with the horse anesthetized and positioned in dorsal recumbency. Through the laryngotomy, the epiglottis is retroverted into view by placing traction on the aryepiglottic fold tissue with sponge or Allis tissue forceps. Applying traction directly to the epiglottic cartilage with forceps should be avoided. The aryepiglottic folds are placed under tension and stabilized in a fan shape with three evenly placed Allis tissue forceps, and the triangular shape of the epiglottis is identified by visual inspection and palpation. The outstretched aryepiglottic fold is incised on the midline with Metzenbaum scissors to within 2 to 3 mm of the epiglottic cartilage tip. The aryepiglottic fold is then cut for a length of about 1 to 1.5 cm parallel to each margin of the epiglottis. Two pieces of mucous membrane are thus excised out of the central portion of the aryepiglottic fold, debulking the membrane and, in most horses, preventing re-entrapment. The laryngotomy is left to heal by second intention, with routine cleaning provided twice daily. Exercise can be resumed after 4 weeks if healing progresses normally. Re-entrainment can occur and is treated by a second excision.

Alternatively, the membrane can be debulked with the horse standing using transendoscopically guided laser excision via the nares. However, care must be taken to avoid thermal damage to the epiglottic cartilage because adhesions and indurated cicatrix often form between the entrapping membrane and the epiglottis, making their delineation difficult and often inducing complications. Owners should be warned that dorsal displacement of the soft palate may be a sequel to correction of epiglottic entrapment regardless of the technique performed, particularly in horses with severe epiglottic hypoplasia.

Acute Epiglottitis
Acute epiglottitis is manifested endoscopically by edema, reddening, and thickening of the epiglottis (Fig. 44-24). Occasionally, the cartilage tip of the epiglottis is exposed. There may be extensive reddening or purple swelling of the
mucous membrane ventral to the epiglottis, elevating the epiglottis dorsally into an abnormal axis. The cause is unknown but the problem is seen most commonly in racehorses. The chief complaint is usually respiratory noise and exercise intolerance or coughing.

Exercise should be discontinued. Most horses respond well to systemic nonsteroidal anti-inflammatory and antimicrobial medications and pharyngeal sprays containing anti-inflammatory medication. Initially, systemic corticosteroids may be useful in reducing severe inflammation. Substantial improvement in endoscopic appearance is usually seen in 7 to 14 days. Most affected horses recover completely and successfully return to work. However, long-term complications occur about 50% of the time and include epiglottic deformity, epiglottic entrapment, or intermittent or persistent dorsal displacement of the soft palate.76

Subepiglottic Cysts
Subepiglottic cysts are particularly prevalent in young Thoroughbred and Standardbred racehorses, suggesting a possible congenital condition.77,78 In young foals, subepiglottic cysts may cause coughing, dysphagia, and aspiration pneumonia.79 Subepiglottic cysts may apparently be acquired, because they are occasionally diagnosed in older horses with no previous history of respiratory tract problems. Older horses are usually presented with a complaint of respiratory noise, coughing and even dysphagia if the cyst is large.78

Diagnosis
A diagnosis of a subepiglottic cyst is made on endoscopic examination. A round or oval, smooth, pink, fluctuant, mucosa-covered mass (15 to 40 mm) can be seen beneath the epiglottis (Fig. 44-25). The epiglottis may be asymmetrically elevated slightly above the soft palate by the cyst. Some larger, more fluctuant subepiglottic cysts may occasionally at rest or during swallowing slip beneath the soft palate into the oral pharynx, temporarily obscuring the cyst from view and causing the epiglottis to have a normal interface with the soft palate. Concurrent intermittent or persistent epiglottic entrapment by the aryepiglottic folds can occur. Lateral laryngeal radiography or contrast pharyngography may be useful in helping to define the location and size of the cyst.

An oral endoscopic and digital examination can reveal the exact size and position of the cyst. The horse is anesthetized, positioned in lateral recumbency, and nasotracheally intubated to allow unrestricted access to the oral pharynx. With a mouth speculum in position, the tongue is extended and the soft palate is digitally displaced above the epiglottis. The cyst can be felt beneath the epiglottis as a variably sized, smooth, fluctuant mass projecting from the area of the epiglottic base superficial to the hyoepiglotticus muscle. The cyst is submucosal in origin, hence the cyst base may be poorly defined (sessile) rather than reduced to a distinct narrow (pedunculated) stalk. Once the examination is complete, the horse may be placed in dorsal recumbency for approach via laryngotomy or left in lateral recumbency for an oral approach (see “Treatment,” next). On histopathologic examination, subepiglottic cysts are usually lined with a combination of stratified squamous and pseudostratified columnar epithelium. Mucous glands, dilated ducts, and a homogeneous eosinophilic mucus are usually present.

Treatment
Removal of the secretory lining is important. If the cyst is merely punctured and drained, the cyst usually seals over and refills within days. Removal of an excessive amount of oral pharyngeal mucosa overlying the cyst may result in cicatricization beneath the epiglottis, possibly altering the
normal range of motion or disrupting the normal synchrony between the epiglottis and the soft palate. Cicatrization after subepiglottic cyst removal may result in clinically significant problems with either intermittent or persistent dorsal displacement of the soft palate.78

Subepiglottic cysts may be removed through a laryngotomy with the horse positioned in dorsal recumbency under general anesthesia.70,79 The epiglottis is gently retroverted into view by grasping the aryepiglottic folds with a sponge or Allis tissue forceps. By elevating the epiglottic tip, the cyst can be palpated on the ventral epiglottic surface. The mucosa is sharply incised over the cyst and the cyst is excised submucosally with Metzenbaum scissors. The mucosal incision is usually left to heal by second intention or it may be sutured with 3-0 to 5-0 synthetic absorbable suture. The laryngotomy is left open to heal by second intention. Exercise is resumed in 3 to 4 days if the laryngotomy has healed routinely and follow-up endoscopy is normal.

Two techniques are available for excision of subepiglottic cysts via an oral approach.78 The horse is anesthetized, positioned in lateral recumbency and nasotracheally intubated. After the cyst is evaluated by palpation, it is visualized on a television monitor with a videofibercope. Traction is placed on the mucosa and the underlying cyst with 600-mm bronchoesophagoscopic grasping forceps (Universal bronchoesophagoscopic grasping forceps, 600-mm length, 8280.62, Richard Wolfe Medical Instrument Corporation, Rosemont, Ill). Using an Nd:YAG laser or a diode laser with a 600-µm sculpted fiber, a fusiform incision into the mucosa over the cyst is made transendoscopically with 15 to 18 W of power. Laser energy is then used to excise the cyst membrane submucosally. Occasionally, a small amount of digital dissection is necessary to free the cyst's final attachments. Alternatively, an electrocautery snare may be applied or a cyst snare can be fashioned from a mare urinary catheter and obstetrical wire and used to excise the cyst at its base, taking extreme caution to remove as little overlying mucosa as possible. In either technique, hemorrhage is minimal and the defect created is left to heal by second intention.

Transendoscopic laser or electrocautery excision can be performed with the horse sedated and cross-tied in stocks. This technique is usually reserved for small cysts that can be easily manipulated to a position above the palate. The cyst is anesthetized topically through polyethylene tubing introduced into the biopsy channel of the videofibercope. Five to 10 mL of local anesthetic solution dripped over the cyst will induce local anesthesia in about 5 minutes. The 600-mm bronchoesophagoscopic forceps are introduced up the opposite nasal passage as the endoscope and the mucosa overlying the cyst is grasped. A fusiform mucosal incision and submucosal dissection of the cyst lining is then performed (as previously described under oral approach) using either an Nd:YAG or a diode laser and a 600-µm sculpted fiber.73

**Aftercare**

Postoperative inflammation and pain are controlled with a combination of corticosteroids, nonsteroidal anti-inflammatory medication, and pharyngeal sprays as needed (see “Postoperative Management,” p. 574). Exercise is restricted until the pharynx appears endoscopically normal, which is usually within approximately 21 days. In horses with concurrent epiglottic entrapment, removal of the subepiglottic cyst usually corrects the epiglottic entrapment because of removal of a small portion of mucosa. Foals with concomitant aspiration pneumonia should be treated with broad-spectrum antimicrobial agents based on culture and sensitivity of tracheal aspirates before excision of the cyst.

**Dorsal Epiglottic Abscess**

Dorsal epiglottic abscess is a rare disease that causes coughing, respiratory noise, and exercise intolerance.60 Palpation of the laryngeal cartilages may elicit pain. On endoscopic examination, there is a smooth, well-circumscribed, round or oval swelling on the dorsal epiglottic surface. Intermittent dorsal displacement of the soft palate may be observed. The abscess can be incised and drained transendoscopically on an outpatient basis with a contact Nd:YAG or diode laser using a sculpted fiber or chisel probe. After decompressing the abscess, debridement can be achieved with 600-mm-long bronchoesophagoscopic grasping forceps. The abscess cavity can be lavaged transendoscopically, if desired, with 240 polyethylene tubing and a dilute 1:10 chlorhexidine solution in physiologic saline.

Aftercare includes stall confinement and exercise restricted to hand-walking. Nonsteroidal anti-inflammatory medication and systemic antibiotics (procaine penicillin G given intramuscularly twice daily) are given at recommended dosages for 3 days. The abscess usually appears to be healed on endoscopic reexamination approximately 10 days postoperatively. In a small number of cases, clinical signs resolved and the horses resumed normal exercise without recurrence of the abscess.80

**Subepiglottic Granulomas**

Subepiglottic granulomas originate as an acute ulceration of the aryepiglottic fold in the ventral aspect of the epiglottis. In response to infection or chronic irritation, excessive granulation tissue forms. This tissue may be confused with subepiglottic cysts. Clinical signs usually include exercise intolerance and occasionally coughing and dysphagia. Large lesions may disrupt the normal interaction between the epiglottis and the soft palate.

**Treatment**

Small granulomas and ulcers respond to antimicrobial and anti-inflammatory medical therapy as long as the horse has received forced rest for approximately 4 to 6 weeks. In nonhealing ulcers, enlargement of the granulation tissue frequently occurs when the horses are returned to exercise. In these cases, excision either orally or through a ventral laryngotomy is indicated. Sharp surgical excision alone (performed through a ventral laryngotomy) may not result in complete resolution of the problem. Therefore, sterilization of this area with laser cautery of the surface after resection is indicated. Alternatively, laser photo ablation of the surface of the granulation tissue can be performed with...
the sculpted fiber using contact technique. It is imperative that extended periods of rest (up to 60 days) accompany any treatment of this condition.80

**Epiglottic Hypoplasia/Flaccidity and Epiglottic Deformity**

**Diagnosis**

Epiglottic hypoplasia/flaccidity and epiglottic deformity have been associated with dorsal displacement of the soft palate and epiglottic entrapment, both of which are causes for abnormal respiratory noise and exercise intolerance.66-75,78,82-85 On endoscopic examination, the hypoplastic epiglottis in the adult horse appears short and narrow, particularly from midbody to the tip, or it may appear very thin (Fig. 44-26). The epiglottic contour may appear flaccid, conforming excessively to the shape of the underlying soft palate. In some horses, the epiglottic border is irregular or rounder and much flatter than normal. Occasionally, the epiglottis has a very shrunken, bumpy, or wrinkled and deformed appearance. Easily induced intermittent or persistent dorsal displacement of the soft palate may be observed during the endoscopic examination. Lateral laryngeal radiography and contrast pharyngography may provide additional information regarding thyroepiglottic length, epiglottic thickness and contour, and the relationship of the epiglottis to other adjacent pharyngeal structures. If the soft palate is persistently displaced dorsally, endoscopy and digital palpation of the epiglottis per os with the horse anesthetized, positioned in lateral recumbency, and nasotracheally intubated may provide useful information on the extent of the problem. Epiglottic hypoplasia severe enough to result in persistent dorsal displacement of the soft palate is associated with a guarded to poor prognosis for optimal exercise potential.83,84 Other underlying problems causing dorsal displacement of the soft palate, such as epiglottic entrapment or subepiglottic cicatrix formation or granulation tissue, can also be fully assessed through a detailed endoscopic and digital oral examination. However, persistent dorsal displacement of the soft palate may occur secondary to severe epiglottic hypoplasia without any other underlying abnormalities or previous surgical intervention.84

Because epiglottic hypoplasia/flaccidity in adult horses is thought to contribute to epiglottic entrapment and intermittent dorsal displacement of the soft palate, the epiglottis is routinely scrutinized during pre-purchase endoscopic examinations in yearling Thoroughbreds. However, no correlation could be found between the appearance of a hypoplastic/flaccid epiglottis in the standing adult horse and dorsal displacement of the soft palate during exercise on a high-speed treadmill.86 Additionally, these same visual epiglottic abnormalities in yearlings could not be significantly correlated with racing performance.17 It is now recognized that the upper airway of yearling and adult horses differ. Compared with adult horses, yearlings have a shorter, narrower, and more flaccid-appearing epiglottis normally, and judgments about epiglottic appearance should be reserved until the horse reaches maturity, except in very severe cases.

**Treatment**

Epiglottic augmentation is performed only in the adult horse to increase the mechanical rigidity of the epiglottis and to make the hypoplastic/flaccid epiglottis more resistant to dorsal displacement of the soft palate. Several materials including collagen and autogenous and allogeneic cartilage grafts have been evaluated, but epiglottic augmentation with polytetrafluoroethylene (Polytef Paste; Polytetrafluoroethylene Teflon paste, Mentor polytef paste for injection, Mentor O & O, Inc. Norwell, Mass) has proved to be the most useful.57,88 Experimentally, in the normal epiglottis polytetrafluoroethylene paste injected submucosally on the ventral epiglottic surface through a laryngotomy (Fig. 44-27) using an Arnold-Bruning syringe (Arnold-Bruning intracordal injection syringe, catalog No. 7754, Storz Instrument Company, St. Louis, Mo) (Fig. 44-28) resulted in an increased thickness of approximately 29% to 40% along the margins and midline88 (Fig. 44-29). Epiglottic length was not increased. Polytetrafluoroethylene paste functions by inciting a sterile granulomatous reaction that is incorporated in fibrous connective tissue.

In two studies, an approach to management of intermittent dorsal displacement of the soft palate that most often combined surgical techniques and always included epiglottic augmentation improved racing performance in 66% of treated horses with poor racing performance attributable to epiglottic hypoplasia/flaccidity.69,70

**Epiglottic Retroversion**

**Diagnosis**

Epiglottic retroversion is a condition in which the epiglottis assumes a position dorsal to the soft palate and retroverts into the opening of the glottis during inspiration and returns to its normal position with each expiration.79 Resting endoscopic examination of the pharynx and larynx can appear normal, or on occasion the epiglottis may project slightly above the soft palate. A high-speed treadmill exami-
nation is necessary to confirm the diagnosis (Fig. 44-30). Retroversion of the epiglottis enables visualization of the ventral (lingual) surface of the epiglottis, but at no time does the soft palate elevate or displace dorsal to the epiglottis. In one horse, the epiglottis rolled up in a tube-like fashion and pointed dorsally, but it did not retroflex into the glottis. During exercise, a respiratory noise may be heard.

**Etiology**

Experimentally, both local anesthesia of the geniohyoid muscle and local anesthesia of the hypoglossal nerves within the guttural pouch have produced epiglottic retroversion during exercise in normal horses.\(^\text{35}\) Trauma or inflammation of the normal hyoid musculature or the hyoepiglotticus or geniohyoid muscles may precede epiglottic retroversion.

**Treatment**

Two horses with this rare problem were treated by epiglottic augmentation with polytetrafluoroethylene paste injected submucosally on the lingual epiglottic surface. One Standardbred was able to return to racing and competed successfully, including winning several races, and one Thoroughbred was retired when it continued to make noise during training after undergoing surgery. A prosthetic suture placed between the epiglottis and the thyroid cartilage was used to stabilize the epiglottis in a racing Standardbred, which allowed it to return to racing.\(^\text{33}\)

**Axial Deviation of the Aryepiglottic Folds**

**Diagnosis**

Axial deviation of the aryepiglottic folds occurs during maximal exertion and causes dynamic upper respiratory tract obstruction. A diagnosis cannot be made during resting endoscopic evaluation but requires videoendoscopic examination during high-speed treadmill exercise (Fig. 44-31, A). It is a distinct entity from intermittent dorsal displacement. In a study of 15 affected horses, 80% were racing Thoroughbreds, 13% were racing Standardbreds, and 7% were racing Arabians. Abnormal respiratory tract noise and exercise intolerance were the most common clinical manifestations.\(^\text{34}\) The condition is almost always bilateral, but unilateral involvement, if present, has been reported to be right-sided.\(^\text{35}\)
Treatment

Transendoscopic laser surgery using an Nd:YAG or a diode laser with a 600-µm sculpted tip fiber in contact fashion can be performed on the conscious, standing horse or with the horse anesthetized. The tissue that is collapsing into the airway during exercise is grasped and placed under tension with 600-mm bronchoesophagoscopic grasping forceps, and an approximately 2-cm-wide triangle is excised transendoscopically. Alternatively, this surgery can be performed through a laryngotomy in the anesthetized horse. Allis tissue forceps can be used to grasp the tissue, and Metzenbaum scissors are used to trim the redundant tissue (see Fig. 44-31, B). No suturing is necessary.

Figure 44-29. A, Twenty-four hours after Teflon injection in the epiglottic fold, the epiglottis becomes edematous. B, Thirty days after injection, the epiglottis is clearly thickened and more substantial when compared with its appearance before surgery (see Fig. 44-26). Videoendoscopic appearance of epiglottic retroversion during the high-speed treadmill examination.

ANATOMY

Guttural pouches are paired extensions of the eustachian tubes that connect the pharynx to the middle ear. They are found in perissodactyls, such as equids, tapirs, some species of rhinoceros (except for the white rhinoceros), some bats, a South American forest mouse, and hyraxes.

The pouches are separated from each other on the midline by the rectus capitis ventralis and the longus capitis muscles and the median septum. Each is in close contact rostrally with the basisphenoid bone, ventrally with the retropharyngeal lymph nodes, pharynx, and the esophagus, caudally with the atlantooccipital joint, laterally with the digastricus muscle and the parotid and mandibular salivary glands, and dorsally with the petrous part of the temporal bone, tympanic bulla, and auditory meatus. Each guttural pouch is divided ventrally into a medial and a lateral compartment by the stylohyoid bone, and it communicates with the pharynx through the pharyngeal orifice of the eustachian tube. The pharyngeal orifice is a funnel-shaped opening in the dorsolateral aspect of the pharynx that forms an oblique slit, rostral and ventral to the dorsal pharyngeal recess. The small end of the funnel opens into the guttural pouch. The medial lamina of each opening is composed of fibrocartilage directed in a rostroventral-to-caudodorsal direction. The capacity of guttural pouches in adult horses is 472 ± 12.4 mL and the lateral compartment is approximately one third of the capacity of the medial compartment.

Clinical signs of important guttural pouch diseases are referable to injury of specific nerves and arteries in the guttural pouch and acoustic system. The internal carotid artery (ICA), cranial cervical ganglion, cervical sympathetic trunk, and vagus, glossopharyngeal, hypoglossal, and the spinal accessory nerves are all contained in a fold of mucous membrane along the caudal wall of the medial compartment (Fig. 45-1). The cranial laryngeal nerve and the pharyngeal branch of the vagus nerve lie beneath the mucosa on the floor of the medial compartment (see Fig. 45-1). The external carotid artery (ECA) lies along the wall of the lateral

---

**Figure 45-1.** Interior of medial compartment of the left guttural pouch, viewed from the lateral aspect in a sagittal section of a horse's head. The section is cut through the stylohyoid process of the petrous temporal bone on a line that divides the guttural pouch into medial and lateral compartments. (IX, glossopharyngeal nerve; X, vagus nerve; XI, accessory nerve; XII, hypoglossal nerve; A, pharyngeal branch of the glossopharyngeal nerve; B, pharyngeal branch of the vagus nerve; C, cranial laryngeal nerve; D, cranial cervical ganglion.) (Redrawn from Freeman DE, Donawick WJ: Occlusion of internal carotid artery in the horse by means of a balloon-tipped catheter: Clinical use of a method to prevent epistaxis caused by guttural pouch mycosis, J Am Vet Med Assoc 1980;176:236.)
compartment and gives off the caudal auricular artery and superficial temporal artery, and it continues as the maxillary artery (MA) along the roof of the guttural pouch. The facial nerve (CN VII) passes for a short distance over the caudal, dorsal aspect of the lateral compartment after it emerges from the stylomastoid foramen. The vestibulocochlear nerve (CN VIII) enters the internal acoustic meatus caudal to the facial nerve and divides into vestibular and cochlear branches that innervate components of the middle ear. This nerve does not enter the guttural pouch but can become involved in guttural pouch diseases that affect the middle ear (e.g., temporohyoid osteoarthropathy). The mandibular nerve, a branch of the trigeminal nerve (CN V), emerges from the foramen lacerum, passes close to the muscular process of the petrous part of the temporal bone, and continues rostrally along the roof of the lateral compartment of the guttural pouch.

The guttural pouch is lined with pseudostatified ciliated epithelium containing goblet cells in both adults and foals. The guttural pouch mucosa has the ability to clear foreign substances, but this ability varies among different regions of the epithelium. In a study on the distribution of various immunoglobulin isotypes and sub-isotypes in the guttural pouch mucosa of healthy horses, IgGa was found in the guttural pouch mucosa, mucosal lymph nodules, and submucosal lymph nodules. IgM was scattered in the mucosal lymph nodules and in the germinal centers of the submucosal lymph nodules. IgGc was recognized only in the submucosal lymph nodules, and IgA was detected in glandular epithelial cells and the surface layer of the mucosal epithelium.

Possible functions of the guttural pouches include pressure equilibration across the tympanic membrane, contribution to air warming, a resonating chamber for vocalization, and a flotation device. A role more recently proposed, on the basis of measurement of lower arterial temperatures in the cerebral side of the internal carotid artery compared with the cardiac side, is brain-cooling. Based on cadaver studies, opening of the pharyngeal orifice of the guttural pouch involves the levator and tensor veli palatini muscles and the pterygopharyngeus and palatopharyngeus muscles. Passive opening of the auditory tube involves a reduced tone in the stylopharyngeus and pterygopharyngeus muscles, accompanied by increased inspiratory pressure. Although guttural pouch filling was previously reported to occur on expiration, the latter study demonstrated that filling occurs on inspiration.

**EXAMINATION**

The guttural pouches are examined by external palpation, endoscopy, and radiography. Enlargement caused by empyema (purulent material in the pouches), but particularly by tympany (air engorgement), can be palpated externally. Guttural pouch endoscopy provides the most information regarding guttural pouch disease. Nonspecific evidence of guttural pouch disease, such as collapse of the pharynx and blood or pus draining from the pharyngeal orifice, can be found on endoscopic examination of the pharynx. However, blood or pus from other respiratory sources may be aspirated into the guttural pouch opening and appear to drain from it, so that direct endoscopic examination of the pouches must be performed (Fig. 45-2). With the horse mildly sedated, the biopsy instrument is passed through the biopsy channel of the endoscope and used to guide the endoscope into the guttural pouch. The endoscope is placed so that the biopsy forceps is as close as possible to the lateral wall of the pharynx until successful insertion into the guttural pouch is achieved. Both pouches can be entered in this manner with the endoscope in the same nostril. Alternatively, the pharyngeal opening can be levered open with a Chamber’s catheter to allow the endoscope to enter the pouches.

Lateral radiographic projections of the guttural pouches can demonstrate fluid lines, fractures and exostoses of the stylohyoid bone, radiopaque foreign bodies, and space-occupying masses. Air distention, as in tympany, can increase dimensions of the affected guttural pouch, sometimes beyond the second cervical vertebra. A dorsoventral or ventrodorsal projection is best used to image the stylohyoid bones and temporohyoid articulation. Computed tomography can provide an alternate imaging modality, especially for imaging of the stylohyoid bone, inner ear, and petrous temporal bone in cases of temporohyoid osteoarthropathy. Ultrasonography can be used to demonstrate soft tissue lesions in the guttural pouches, such as tumors or muscle damage and associated submucosal hemorrhage.

A percutaneous centesis technique through Viborg’s triangle has been described for guttural pouch lavage and collection of samples for cytologic and microbiologic examinations. The normal cytologic pattern is less than 5% neutrophils, a large proportion of ciliated columnar epithelial cells, a few nonciliated cuboidal epithelial cells, and less than 1% monocytes, lymphocytes, and eosinophils. The proportion of neutrophils is important, with less than 5% being considered normal and greater than 25% being considered abnormal. There is a high correlation between a high cytologic score and the presence of pathogenic bacteria such as *Streptococcus equi*. The cytologic gradings and

![Figure 45-2. Normal endoscopic anatomy of right guttural pouch. neutrophil concentrations of guttural pouch washings are increased in horses whose heads are restrained for more than 12 hours, as would occur during long transportation.22 Washings from these horses are more likely to contain bacteria and yield potentially pathogenic bacteria.22

DISEASES OF THE GUTTURAL POUCH

Tympany

Tympany, as the name implies, is the distention of the guttural pouches with air under pressure, sometimes accompanied with some fluid accumulation. This condition is usually unilateral but can be bilateral and is more common in fillies than in colts.23 In 51 foals with guttural pouch tympany seen at a German clinic between 1994 and 2001, there were approximately three times as many fillies as colts,24 regardless of breed.25,26 There were significantly more Arabian and Paint horse foals compared with the breed distribution of hospitalized foals at the same clinic.24 In the 27 Arabian purebred foals affected with guttural pouch tympany, many were from the same stud farm and some were full or half siblings. Complex segregation analysis showed that a polygenic and a mixed monogenic–polygenic model best explained the segregation of Arabian foals with this disease.27

Possible causes include a mucosal flap that acts as a one-way valve and traps air and fluid in the pouch, inflammation from an upper airway infection, persistent coughing, and muscle dysfunction.28 In most cases, there is no gross anatomic abnormality at the guttural pouch opening.

Clinical Signs

Guttural pouch tympany develops in foals shortly after birth and up to 1 year of age. The affected guttural pouch is distended with air to form a nonpainful, elastic swelling in the parotid region. Although the swelling is most prominent on the affected side, it can extend across the neck and give the impression of bilateral involvement. Severe distention is usually well tolerated and does not interfere with growth and development, but it can cause dyspnea, dysphagia, and inhalation pneumonia. Secondary empyema is not uncommon.

Diagnosis

Diagnosis is based largely on clinical signs. On endoscopic examination, the pharyngeal openings usually appear normal, but the roof of the pharynx can be collapsed. Guttural pouch enlargement with air and fluid can be seen on radiographs. Distinguishing between unilateral and bilateral tympany can be difficult on radiographs, but usually they can be defined on direct endoscopy of each pouch.29

Treatment

Temporary alleviation can be achieved by needle decompression or by placing an indwelling catheter in the pharyngeal orifice; however, surgery is required for definitive treatment. The affected guttural pouch is usually entered through Viborg’s triangle or through a modified Whitehouse approach (discussed later). The median septum can be fenestrated by removal of a 2-cm² segment to allow egress of trapped air from the tympanitic pouch through the normal side.28 (Fig. 45-3). A Chamber’s mare catheter or, preferably, a lighted fiberoptic endoscope can be inserted into the healthy pouch to elevate the septum toward the incision and to demonstrate it (see Fig. 45-3). When bilateral involvement is suspected, the fenestration procedure can be

Figure 45-3. Method for creating a fenestration between the abnormal and normal guttural pouches in a foal with unilateral tympany. The affected guttural pouch (on the left side) is approached through an incision in Viborg’s triangle, and a Chamber mare catheter in the right guttural pouch is used to elevate and expose the median septum. In the expanded view, a pair of scissors has been placed to start fenestration (broken line). (Redrawn from Milne DW, Fessler JF: Tympanitis of the guttural pouch in a foal, J Am Vet Med Assoc 1972;161:61; and Deen T: Surgically correcting guttural pouch tympany, Vet Med 1988;83:592.)
combined with removal of a small segment (1.5 x 2.5 cm) of the medial lamina of the eustachian tube and associated mucosal fold within the guttural pouch orifice; this forms a larger opening into the pharynx. The approach incision can be closed or left open to heal by second intention. Systemic antibiotics are given if needed.

Transendoscopic electrocautery can be used to create a fenestration in the septum and to make a fistula into the guttural pouch through the pharyngeal recess. A high-powered diode or a neodymium-yttrium-aluminum-garnet (Nd:YAG) laser can also be used through a transendoscopic approach to create the fenestration. This can be carried out as a standing procedure or with the horse under general anesthesia. An alternative and easier method is to create a salpingopharyngeal fistula using the laser under videoendoscopic control in the wall of the pharynx, caudal to the guttural pouch opening. A Foley catheter is placed through the fistula for 7 to 10 days to act as a stent and to allow lavage of the guttural pouch.

Prognosis
The prognosis for complete recovery and a successful racing career is favorable after median septum fenestration by any method. A surgical laser technique was used on 50 foals in one clinic and was successful in 35 foals after one treatment and in 15 foals after two treatments. Long-term follow-up information, available for 44 of the 50 treated horses, revealed no deaths related to the disease or treatment and that all horses up to 2 years of age were healthy.

Secondary empyema and pneumonia usually resolve spontaneously after successful treatment of the tympany; however, the prognosis is guarded for foals that have aspiration pneumonia and dysphagia secondary to nerve damage induced during surgical correction. The fenestration procedure can fail if the newly created opening seals or the condition is bilateral. Resection of the mucosal fold can fail if swelling and inflammation along the cut edges close the pharyngeal orifice. The salpingopharyngeal fistula may seal if the catheter does not stay in place for the period required for the fistula to mature. Horses treated with this method have responded favorably.

Empyema
Empyema of the guttural pouches is defined as the presence of purulent material (Fig. 45-4), and chondroids within the one or both guttural pouches. Chondroids consist of inspissated purulent material (usually numerous individual round balls) that forms in some cases (Fig. 45-5). Empyema can affect horses of any age but usually occurs in young animals. Upper respiratory tract infections (especially those caused by Streptococcus), abscessation and rupture of retropharyngeal lymph nodes into the guttural pouch (see Fig. 45-4), infusion of irritant drugs, fracture of the stylohyoid bone, congenital or acquired stenosis of the pharyngeal orifice, and pharyngeal perforation by a nasogastric tube may cause empyema. Persistence of guttural pouch infection in asymptomatic long-term carriers could be responsible for recurrent outbreaks of strangles. In one study of 91 horses with guttural pouch empyema, 21% had chondroids, and the horses with chondroids were more likely to have retropharyngeal and pharyngeal swelling than those without this complication. The number of chondroids present is variable, ranging from one to many (see Fig. 45-5), and both guttural pouches can be affected. Duration of infection does not appear to correlate with development of chondroids.

Clinical Signs
Clinical signs include intermittent nasal discharge in most cases, swelling of adjacent lymph nodes, parotid swelling and pain, extended head carriage, excessive respiratory noise, and difficulties in swallowing and breathing. In rare cases, guttural pouch empyema can cause pharyngeal and laryngeal paresis.
**GUTTURAL POUCH**

**Diagnosis**

On endoscopic examination, a purulent discharge can be seen at the pharyngeal orifice of the affected side, with pharyngeal collapse in some horses. Fluid accompanied by masses seen within the guttural pouch on standing lateral radiographs is suggestive of chondroids.\(^4^7\) Fluid aspirates or saline washings can be taken from the guttural pouch for culture and sensitivity testing; however, results should be interpreted with caution because microorganisms can be retrieved from the normal guttural pouch and upper respiratory tract. Horses that are carriers of, or are infected with, *S. equi* in the guttural pouches can be identified by culture and polymerase chain reaction tests with repeated swabs.\(^4^8\)

**Treatment**

In acute cases, daily irrigation with physiologic saline solution is usually effective. An indwelling catheter, devised from polyethylene 240 tubing with heat-formed coils at one end, can be used for this purpose. Alternatively, a commercially available guttural pouch catheter (Cook Veterinary Projects, Bloomington, Ind; Mila International, Florence, Ky) or one fashioned from a polypropylene dog urinary catheter can be used. Coiled catheters can be straightened to facilitate insertion by inserting a coaxial wire or by passage through a larger curved catheter. The coiled end of the catheter is placed endoscopically within the pouch, and the free end is secured by a suture to the alar fold. A Foley catheter can also be used, but it should be advanced until the end is completely in the pouch because distention of the balloon within the pharyngeal opening could cause pressure necrosis. In larger horses, standard Foley catheters are not long enough to reach the guttural pouch. Alternatively, the pouch can be flushed through the biopsy channel of the endoscope, which has the advantage of delivery of the flush solution to areas coated with purulent material. After 7 to 10 days, irrigation should be interrupted briefly to assess the response, with the awareness that this treatment can cause some inflammation.

Hydrogen peroxide or concentrated antiseptic solutions should not be infused because they are irritating and can induce neuritis of the cranial nerves. Topical antibiotics are rarely effective because the contact period is too brief and many are inactivated by the products of inflammation present in the purulent material. Dilute povidone-iodine (1%) is more effective than concentrated solutions because free iodine dissociates more readily from the organic carrier at low concentrations; however, iodine can be neutralized by exudates.\(^3^9\) In one horse with empyema that did not respond to saline lavage, infusion of acetylcysteine on four occasions appeared to hasten resolution.\(^4^0\) However, despite its ability to disrupt disulfide bonds of mucoproteins, acetylcysteine did not alter the viscosity of purulent material in clot tubes compared with the use of saline alone.\(^4^0\) Systemic antibiotics are rarely indicated unless the response to topical treatment is poor or the infection is severe. Drugs of choice are a potentiated sulphonamide, penicillin, or cefiofur for at least 21 days.\(^4^0\) Nonsteroidal anti-inflammatory drugs may be used as needed.

In severely dyspneic horses caused by guttural pouch distention, a tracheotomy should be performed. If the response to medical treatment is poor or if the purulent material becomes inspissated or forms chondroids, surgical drainage of the guttural pouch should be considered (discussed later). Chondroids can also be removed by maceration, followed by saline lavage or extraction by endoscopically guided grabbing forceps, a basket snare, or a memory-helical polyp retrieval basket (Cook Ltd, Bloomington, Ind).\(^4^0\) Another technique involves repeated section of each mass by a diathermic snare (Olympus Optical Co, Irving, Tex) or a wire loop, with removal by suction, lavage, or extraction by basket-type endoscopic forceps (Gomco Equipment, Chemetron Medical Products, Buffalo, NY).\(^4^1\) In one study, 44% of horses with chondroids were treated successfully by these noninvasive methods,\(^4^5\) although removal by these methods can take a long time. If empyema is the result of occlusion of guttural pouch openings by adhesions, this occlusion may be relieved by blunt division through a surgical approach to the guttural pouch interior.\(^4^5\) Chronic empyema of the guttural pouches, possibly unresponsive to medical therapy because of poor drainage through the pharyngeal ostia, can be successfully treated by using a laser to establish a permanent pharyngeal fistula into the guttural pouch.\(^4^2\)

**Prognosis**

Response to medical treatment is usually satisfactory, and surgery is rarely indicated. Neurologic signs usually resolve once the infection is brought under control by medical or surgical treatment.

**Guttural Pouch Mycosis**

Guttural pouch mycosis affects the roof of one guttural pouch, rarely both. There is no apparent age, sex, breed, or geographic predisposition to this disease. The cause of guttural pouch mycosis is unknown, although *Aspergillus* can be identified in the lesion. The typical lesion of guttural pouch mycosis is a diphtheritic membrane of variable size, composed of necrotic tissue, cell debris, a variety of bacteria, and fungal mycelia.\(^2^8\) Aneurysm formation does not appear to precede or follow arterial invasion consistently and, therefore, is not essential to the pathogenesis of arterial rupture.

**Clinical Signs**

The most common clinical sign is moderate-to-severe epistaxis, which is caused by fungal erosion of the internal carotid artery in most cases\(^4^3\) (Fig. 45-6) and of the external carotid and maxillary arteries in approximately one third of cases\(^4^7\) (Fig. 45-7, and see Fig. 45-2). However, any branch of the external carotid artery, such as the caudal auricular artery, can be affected. Several bouts of hemorrhage usually precede a fatal episode. Mucus and dark blood continue to drain from the nostril on the affected side for days after acute hemorrhage ceases.

The second most common clinical sign is dysphagia caused by damage to the pharyngeal branches of the vagus and glossofaryngeal nerves\(^4^4\) (see Fig. 45-6). Aspiration pneumonia may develop in severe or protracted cases. Abnormal respiratory noise can arise from pharyngeal
Paresis or laryngeal hemiplegia, the latter as a result of recurrent laryngeal nerve damage. Horner’s syndrome may develop from damage to the cranial cervical ganglion and postganglionic sympathetic fibers. The classic signs associated with this denervation are ptosis, miosis, and enophthalmos; patchy sweating; and congestion of the nasal mucosa. The reason for equine sweat glands to increase their activity when denervated is unclear. Equine sweat gland myoepithelium is predominantly under α2-adrenergic control, with additional α-adrenergic input from receptors. However, sweating after neurectomy may be caused by increased peripheral vasodilation, which increases blood flow and skin temperature. Ptosis is caused by a decreased tone of the superior tarsus muscle, and it is assessed by observing eyelash angles from a frontal view. Pupillary response to decreased sympathetic tone in horses is variable, and the maximal difference in pupil size is usually slight. Enophthalmos, which is the result of decreased smooth muscle retrobulbar tone and unopposed activity of the striated retractor bulbii muscle, is rarely obvious and usually evident as a slight protrusion of the nictitating membrane.

Less common signs of guttural pouch mycosis are parotid pain, nasal discharge, abnormal head posture, head shyness, sweating and shivering, corneal ulcers, colic, blindness, locomotion disturbances, facial nerve paralysis, paralysis of the tongue, and septic arthritis of the atlantooccipital joint.

**Diagnosis**

Endoscopy is critical for diagnosis, and it should be combined with history and clinical signs. On endoscopic examination of a horse with epistaxis, blood can be seen draining from the pharyngeal orifice. In horses with dysphagia, the roof of the pharynx can be collapsed, the soft palate can be displaced, and the nasopharynx may contain food material. The lesion appears as a white, tan, and black diphtheritic membrane on the roof of the affected guttural pouch, and its size can vary but bears no relationship to the severity of clinical signs (see Fig. 45-6). Part of the diphtheritic membrane can coat the stylohyoid bone and the bone can be thickened, but clinical signs usually do not develop from this change. Fistulas may form into the opposite guttural pouch and pharynx. The presence of serum antibodies to *Aspergillus fumigatus* detected by enzyme-linked immunosorbent assay (ELISA) cannot distinguish between horses with guttural pouch mycosis and healthy horses.

**Treatment**

**NONSURGICAL TREATMENT**

The response to topical treatment is generally slow and inconsistent. Daily direct lavage through the endoscope can macerate the diphtheritic membrane, and the biopsy forceps or cytology brush of the endoscope can be used to detach it, provided any eroded artery was occluded beforehand. Topical povidone-iodine or thiabendazole, with or without dimethyl sulfoxide, has been used with mixed results. Itraconazole at 3 mg/kg twice a day in the feed can be effective against *Aspergillus* and other fungi in the nasal...
passage of horses, but treatment may be required for up to 4 or 5 months. Bioavailability of another triazole antifungal agent, fluconazole, can be sufficiently high after oral and intravenous administration in horses to suggest a potential value in treatment of fungal infections. The response to any treatment method that is measured solely by disappearance of the mycotic lesion should be interpreted with caution because spontaneous regression of the lesion over a variable time course is typical. Horses with blood loss should be treated with polyionic fluids and, if necessary, with blood transfusions, and horses with dysphagia should be fed by nasogastric tube or by esophagostomy and should receive nonsteroidal anti-inflammatory drugs to reduce neuritis.

SURGICAL TREATMENT
The diphtheritic membrane can be detached by gentle swabbing and lavage through a modified Whitehouse approach. This treatment does not eliminate the risk of hemorrhage completely, and it does not retard or reverse progression of neurologic signs, but it does carry the risk of iatrogenic nerve damage and hemorrhage. In horses with epistaxis, the affected artery should be identified by endoscopy and surgically occluded (discussed later). There is some anecdotal but widely accepted evidence that occlusion of the affected artery hastens spontaneous resolution of the mycotic lesion and thereby renders medical therapy unnecessary.

Prognosis
Approximately 50% of horses with hemorrhage die from this complication, but this risk can be abolished or considerably reduced by the occlusion procedures described later. These procedures must be performed as soon as possible after the first bout of hemorrhage to prevent subsequent bouts that could render the horse a poor candidate for anesthesia and surgery.

Although the mycotic lesion disappears with time, neurologic signs can persist. Laryngeal hemiplegia is usually permanent, but recovery has been reported. Some horses with dysphagia do eventually recover, but 6 to 18 months may be required and recovery may be incomplete. Horses can recover from Horner’s syndrome and facial nerve paralysis.

Rupture of the Ventral Straight Muscles
Rupture of ventral straight muscles of the head (the longus capitis muscle and rectus capitis ventralis muscle) is usually caused by trauma, such as falling over backward, and it can cause severe epistaxis. A nondisplaced impaction fracture at the basisphenoid–basioccipital junction associated with this injury can cause neurologic signs from subdural hemorrhage over the cerebral cortex and brain stem. The same injury may occur without causing epistaxis.

Clinical Signs and Diagnosis
Rupture of the ventral straight muscles causes severe epistaxis, as does guttural pouch mycosis. Some horses may show ataxia and other neurologic signs, and hemorrhage from torn muscle into the retropharyngeal tissues can compress the pharynx and even the trachea and cause respiratory obstruction.

Rupture of the ventral straight muscles is distinguished from guttural pouch mycosis by a history of trauma with the former, if such history is available, and by endoscopy. In horses with rupture of the ventral straight muscles, the roof of the pharynx is collapsed and both guttural pouches are affected, usually more so on one side than on the other. Unlike in guttural pouch mycosis, the major arteries and the more caudal aspects of the guttural pouches are not involved, and there is no evidence of a diphtheritic membrane (Fig. 45-8). Although some dark blood can be seen in the most rostral aspect of the pouch, it usually obscures the view of this area. A more complete view of the source of hemorrhage and swollen muscle bellies can be seen by retroversion of the endoscope (Fig. 45-7). After swelling and inflammation from the original injury have subsided, any displaced bone fragment from a basisphenoid–basioccipital avulsion fracture can be seen on endoscopic examination of the medial compartment of the guttural pouch.

On radiographs, partial obliteration of the guttural pouch by increased soft tissue density, soft tissue impingement on the roof of the pharynx, gas in soft tissues of the head and neck, and even avulsions of the basisphenoid bone may be evident (Fig. 45-9). The size and extent of the hematoma and gas in soft tissues can be determined by an ultrasonographic examination.

Treatment and Prognosis
Treatment is stall rest for 4 to 6 weeks, and limiting head and neck movement that could disturb the damaged muscles and precipitate hemorrhage. Antibiotics are given to prevent secondary infections through the disrupted mucosa. The prognosis is good provided there are no neurologic signs, because these can be permanent and life threat-
ening. Severe neurologic signs, such as inability to rise, depression, and sluggish menace response, may be caused by an associated subdural hemorrhage overlying the cerebral cortex and brain stem, and warrant euthanasia.

**Temporohyoid Osteoarthropathy (Middle Ear Disease)**

Temporohyoid osteoarthropathy is a progressive disease of the middle ear and components of the temporohyoid joint, such as the stylohyoid bone, the cartilaginous tympanohyoid, and squamous portion of the temporal bone. Horses of a wide age range and of any breed or either sex can be affected. The cause is thought to be an inner or a middle ear infection of hematogenous origin that spreads to the aforementioned bones, causing them to thicken and the temporohyoid joint to fuse. Other possible causes range from extension of otitis media/externa or guttural pouch infection to a nonseptic osteoarthritis. Although guttural pouch mycosis can involve the same bony structures and temporohyoid articulation, clinical signs of temporohyoid osteoarthropathy are rare with this disease.

Once the temporohyoid joint fuses and the associated bones thicken, forces generated by movement of the tongue and larynx during swallowing, vocalizing, combined head and neck movements, oral or dental examinations, and teeth floating may induce fractures of the petrous part of the temporal bone, resulting in facial nerve (CN VII) and vestibulocochlear nerve (CN VIII) dysfunction. Severe new bone production and inflammation can damage the glossopharyngeal and vagus nerves where they leave the medulla caudal to the vestibulocochlear nerve. After fracture of the petrous temporal bone, middle or inner ear infection could extend around the brain stem and involve additional cranial nerves and hindbrain structures.

**Clinical Signs and Diagnosis**

Early signs include head tossing, ear rubbing, refusing to take the bit, refusing to position the head properly when under saddle, resistance to digital pressure around the base of the ears or on the basihyoid bone, and other nonspecific behavioral changes. The disease can cause an acute onset of signs consistently referable to the vestibulotrochlear nerve, including asymmetrical ataxia, head tilt with the poll to the affected side, and spontaneous nystagmus with the slow component to the affected side. These signs can be revealed or exacerbated by blindfolding. Signs of facial nerve damage, including paresis or paralysis of the ear on the affected side, deviation of the upper lip away from the affected side, decreased tear production, and inability to close the eyes, are evident in most cases. Decreased tear production and inability to close the eyes may cause corneal ulcers, keratoconjunctivitis sicca, and exposure keratitis.

Dysphagia is rare but can result from damage to the glossopharyngeal and vagus nerves. Radiographs of the skull may depict proliferation and osteitis of the affected bones; however, endoscopy of the guttural pouch is in most cases a more sensitive method for detection of stylohyoid bone and temporohyoid joint involvement and hence for making the diagnosis (Fig. 45-10). Computed tomography can precisely demonstrate bony and soft tissue changes in the middle and inner ear.

**Treatment and Prognosis**

Medical treatment includes broad-spectrum antibiotics for infection, nonsteroidal anti-inflammatory drugs to relieve pain and inflammation, and dimethyl sulfoxide to relieve inflammation. Unilateral partial ostectomy of the stylohyoid bone has been used to create a pseudoarthrosis between the cut ends of the bone (Fig. 45-11), which decreases the forces on the ankylosed temporohyoid and thereby prevents skull fractures. In this procedure, approximately 2 to 3 cm of the midbody of the stylohyoid bone is removed (see Fig. 45-11). Although this procedure appears to have merit as a prophylactic measure against more severe bone damage and associated neurologic consequences, it may cause transient dysphagia or injury to the hypoglossal nerve. When performed as a bilateral procedure, it causes permanent problems with prehension. An additional complication of the partial ostectomy is regrowth of the stylohyoid bone approximately 6 months after surgical resection, and recurrence of clinical signs. Because of this complication, a ceratohyoidectomy can be performed as a safer, easier, and more permanent surgical alternative (see Fig. 45-11). For this, the horse is placed in dorsal recumbency and the ventral laryngeal region prepared aseptically. A 10- to 15-cm incision is made in the skin medial to the linguofacial vein on the affected side and centered on the basihyoid bone. The fibers of the ceratohyoidius muscle are separated bluntly until the basihyoid bone is exposed. Rostral to the basihyoid bone, the geniohyoid muscle is separated to expose the ceratohyoid bone and, lateral to it, the hypoglossal nerve. The ceratohyoid–basihyoid synovial joint is identified and disarticulated with cartilage scissors. The transected end of

---

*Figure 45-9. Radiograph demonstrating avulsion fracture of the basisphenoid bone, soft-tissue obliteration of the guttural pouch cavity, soft-tissue impingement on the pharynx, and gas in soft tissues in a horse with ruptured ventral straight muscles of the head. (Courtesy J. Foreman, Louisiana State University.)*
The ceratohyoid bone is grasped and the ceratohyoid bone freed from its attachments to the ceratohyoideus, the hyoideus transversus, and the genioglossus muscles. The hypoglossal nerve and lingual branches of the mandibular and glossopharyngeal nerves are identified and gently retracted to protect them during these steps. The cartilaginous articulation between the ceratohyoid bone and the stylohyoid bone is cut by cartilage scissors, taking care to avoid tension on the bone and temporohyoid joint. The separated muscle fibers and subcutaneous tissues are then apposed using absorbable suture in a simple continuous fashion, and skin closure is routine.

Although the prognosis is good according to one report,73 neurologic signs may persist,71 especially if treatment is delayed. In general, the prognosis for stylohyoid arthropathy is based on the severity of the clinical signs. Some degree of facial nerve paresis can persist.8 The corneal ulcers are difficult to treat, because there is an underlying problem with lid closure and tear production. A temporary tarsorrhaphy may help to manage the ocular complications until facial nerve function returns.

Miscellaneous

Although guttural pouch neoplasia is rare, squamous cell carcinoma,74,75 round cell sarcoma,12 fibroma,76 hemangioma,77 hemangiosarcoma,77 and parotid melanoma have been described.79,80 In one case, bilateral squamous cell carcinoma of the guttural pouches and the left middle ear was initially evident as protrusion of a mass in one external acoustic meatus, without other obvious clinical signs.81 Parotid melanomatosis can appear as multilobular or multiple individual firm lumps in the parotid region of Gray Horses with extension into the guttural pouches (Fig. 45-12) and may cause dyspnea and dysphagia from compression of the nasopharynx and larynx, and facial nerve paralysis from compression of the facial nerve.79,80 In one case, a malignant amelanotic melanoma caused halitosis, nasal discharge and cough by undergoing central necrosis that extended from the guttural pouch into the pharynx.17 The rate of growth of melanomas is variable and can be rapid after a prolonged initial growth,80 but even clinically evident lesions can be well tolerated in sedentary horses and allow years of continued health.79 Smaller lesions may not be evident externally, and it is not unusual to find small discrete and scattered submucosal black areas and even lumps in the guttural pouch of Gray Horses (see Fig. 45-12). These are unlikely to cause problems. Extensive tumors may infiltrate the parotid gland without apparent lymph node involvement. Surgical resection is rarely indicated and is usually impossible in most cases because of the extent of infiltration and the close association with vital structures.80

Fracture of the stylohyoid bone can be secondary to guttural pouch mycosis or trauma.12,28 Bone necrosis can follow, and clinical signs include dyspnea, pharyngeal swelling, empyema, keratoconjunctivitis sicca, and abscessation.12,44,69 Reported foreign bodies include segments of catheters and wire.12,82 Cystic structures have been described as causes of guttural pouch swelling and dyspnea in young horses (Fig. 45-13) and respond favorably to surgical resection and fenestration in the median septum between the two gutteral pouches.83 The cause is unknown, but this lesion could be congenital or acquired.83

**Surgical Drainage of the Guttural Pouch**

The following approaches can be used to open the guttural pouch for removal of pus, mycotic plaques, and foreign bodies and to establish drainage.
Hyovertebrotomy
A 10-cm-long incision is made 2 cm craniad to and parallel with the wing of the atlas (see Fig. 45-14). The dense parotid fascia is incised, and the parotid gland and overlying parotidoauricularis muscle are reflected cranially. The guttural pouch lining is exposed beneath a covering of areolar tissue and grasped with rat-toothed or Allis tissue forceps. It is punctured with the closed tips of scissors or a hemostat, and this opening is enlarged by spreading its edges with a hemostat or the fingers. To establish ventral drainage, the pouch is opened ventrally through an incision in Viborg’s triangle, guided by a finger within the pouch. The hyovertebrotomy can be closed or left partly open for infusion of irrigating solutions.

Viborg’s Triangle Approach
Viborg’s triangle is bordered by the tendon of the sternoccephalicus muscle, the linguofacial vein, and the vertical ramus of the mandible (see Fig. 45-14). A vertical or horizontal incision is made in this area, taking care to avoid the parotid duct and branches of the vagus nerve along the floor of the guttural pouch. The incision is usually kept open with a soft rubber drain to establish ventral drainage.

Whitehouse Approach
With the horse in dorsal recumbency, a skin incision is made on the ventral midline over the larynx (Fig. 45-14). Dissection is continued between the paired sternohyoideus muscles.

Figure 45-12. Endoscopic views of two horses with melanomas in the lateral compartments of their left guttural pouches that were not causing clinical problems. A, Typical melanin staining is scattered along the course of the external carotid artery and branches in an old gray horse without any external evidence of parotid involvement. B, A larger lesion (arrow) fills the lateral compartment and is evident externally as a firm mass over the parotid gland.

Figure 45-13. Bilateral guttural pouch cysts, each in the medial compartment of a Haflinger foal. Arrows point to the stylohyoid bones. This foal had nasal discharge, but the role of the cysts could not be established, there were no other clinical signs referable to them, and they were not treated.
and omohyoid muscles and along the larynx to the affected guttural pouch. The guttural pouch is opened medial to the stylohyoid bone, and care is taken to avoid the pharyngeal branch of the vagus nerve and the cranial laryngeal nerve, which are close to the incision.

Modified Whitehouse Approach
In the modified Whitehouse approach, the skin incision is made along the ventral edge of the linguofacial vein and extends rostrally for about 12 cm from the jugular vein (see Fig. 45-14). The underlying fascia is incised to expose the lateral aspect of the larynx, and blunt dissection is continued until the guttural pouch cavity has been entered. The major advantage of this modification is that dissection is through a natural fascial plane and does not involve an incision between the sternohyoideus and omohyoid muscles.

Advantages of both Whitehouse approaches are direct access to the roof of the guttural pouch, digital access to the lateral compartment, excellent ventral drainage, and simultaneous access through the septum to both pouches. Although both approaches involve deep dissection, they do not appear to have a higher rate of complications than other approaches.

General Comments
Surgery of the guttural pouch through any approach should be a last resort because of risks of iatrogenic nerve damage. Identification of the guttural pouch lining and underlying nerves is difficult, especially in cases in which there is no distention, and can be facilitated by a lighted endoscope inserted into the medial compartment. A fixed structure, such as the stylohyoid bone, should be used as a guide for deep dissection. The mucosa should not be incised with sharp instruments, and retractors should be applied with care to avoid nerve damage. Because all approaches enter the pouch cavity in the same approximate area, none provide less risk of nerve damage than others.

Open incisions in the guttural pouch are cleaned daily, and the guttural pouch cavity should be flushed daily with a nonirritating solution. Open incisions close spontaneously within 14 days, and the infection should also resolve within this time. Postoperative antibiotics can be given.

PROCEDURES FOR ARTERIAL OCCLUSION
In a horse with hemorrhage caused by guttural pouch mycosis, the involved artery or arteries should be occluded by one of the following procedures, or a combination of them, as soon as the diagnosis is made. The vessel to be occluded is determined by endoscopy. If accurate identification is impossible because landmarks are obscured by blood and diphtheritic membrane, all arteries in the pouch should be occluded, and this can be done safely.\(^{58}\) Arteriography\(^{84}\) may also be used to identify the affected vessel and to identify unusual anatomy, but it is not required in all methods or in all cases; however, it does allow more precise and selective occlusion.

Ligation of the Common Carotid Artery and Branches
In horses with guttural pouch mycosis, fatal or severe hemorrhage has followed ligation of the affected internal carotid artery (ICA) and could be attributed to occlusion of the wrong vessel or to retrograde flow from the cerebral arterial circle (circle of Willis).\(^{43,45,85,86}\) A study was performed on six anesthetized adult horses to determine the effects of selective arterial occlusion on blood flow through the common carotid artery (CCA) and its branches, and to thereby establish the most effective ligation for horses with life-threatening hemorrhage from these vessels.\(^{87}\) Compared with control values, flow through the left ICA was reduced to 38% by simultaneous occlusion of the left and right CCA and to 19% by occlusion of the left ICA.\(^{57}\) Occlusion of the left mid-cervical CCA induced retrograde flow through the left ICA that was 40% greater than control flow.\(^{57}\) In the same study, flow through the left ECA was reduced to 30% to 31% of control values by occlusion of the left mid-cervical CCA or by simultaneous occlusion of the left and right CCA.\(^{57}\) Occlusion of the ECA or combined occlusion of the ECA and the major palatine artery reduced flow through the ECA to 1% of control values.\(^{57}\) However, these data provide no information on blood pressure, which could remain sufficient after some of these ligations to cause substantial hemorrhage. Blood pressure in the segment of internal carotid artery in the guttural pouch is not reduced by ligation and is maintained for at least 3 days afterward at the same level as in the contralateral patent artery.\(^{58}\)

Based on the preceding findings, ligation of the ipsilateral common carotid artery in a horse bleeding from the internal carotid artery would increase flow in the affected artery and...
would be contraindicated; however, the same procedure may provide some immediate benefit in horses bleeding from the external carotid artery and its branches, although any such benefit could be temporary. Ligation of the affected ICA would decrease flow but not pressure, so bleeding could persist or recur; however, if access to definitive occlusion procedures is not immediate during a severe bleeding crisis, induction of general anesthesia to quiet the horse and ligation of the affected internal carotid artery could be attempted.

Success with ligation of the internal carotid artery can be attributed to thrombosis distal to the ligation at some time after surgery. To prevent backflow, an additional ligature has been placed distal to the mycotic infection; however, this is difficult because the artery must be ligated deep within the guttural pouch, where it is likely to be obscured by the diphtheritic membrane. The site for ligation of the ICA is immediately distal to its origin, outside the guttural pouch, using a similar but more ventral approach to a hyovertrebrotomy (see Fig. 45-14). The ICA is identified on the cardiac side of the occipital artery and deep to that vessel. In some horses, both arteries arise as a single trunk. If necessary, both ICAs can be ligated simultaneously without any apparent risk.

The external carotid artery can be ligated distal to the origin of the linguofacial trunk through an incision similar to that used for the internal carotid ligation but after extensive rostral dissection. However, this procedure is generally unsuccessful because the external carotid and maxillary arteries have numerous collateral channels that allow retrograde flow to the affected segment.

Although ligation of the major palatine artery could prevent retrograde flow, a combination of this procedure with ligation of the external carotid and internal carotid arteries can cause ischemic optic neuropathy and permanent blindness.

**Balloon Catheter Occlusion of the Internal Carotid Artery**

The balloon catheter technique allows immediate intravascular occlusion of the artery and prevents retrograde flow from the cerebral arterial circle. Risk of retrograde flow is not diminished immediately by ligation alone, because this does not drop blood pressure in the distal segment of artery.

The internal carotid artery is ligated close to its origin, and an arteriotomy is made distal to the ligation (Fig. 45-15). A size 6 French venous thrombectomy catheter (Fogarty-Edwards Laboratories, distributed by American V. Mueller, Chicago, Ill) is inserted through the arteriotomy for a distance of approximately 13 cm. At this distance, the balloon tip of the catheter is arrested at the sigmoid flexure of the internal carotid artery, within the venous sinuses and distal to the site of infection (see Fig. 45-15). Fluoroscopy is not required to confirm placement, but intraoperative endoscopy can be helpful, although this can be difficult if landmarks are obscured by blood or the lesion. The catheter tip should be visible as it passes up the artery, and the balloon can be inflated at intervals to demonstrate its position. However, it does not distend the artery as dramatically as one would like, and this can make it difficult to locate. The balloon is inflated with sterile saline and secured in position by a ligature distal to the arteriotomy, and the redundant portion is buried as the incision is closed.

The horse may resume its usual activity when wound healing is complete and its packed cell volume has returned to normal. Perioperative antibiotics and nonsteroidal anti-inflammatory drugs can be used. It is not necessary to treat the fungal lesion or to remove the catheter after surgery, unless infection tracks along it and invades the surgical incision. For removal of the catheter, the horse is sedated and local anesthetic is infiltrated along and rostral to the original incision. A cut-down procedure is used to locate the coils of the catheter, which are then freed up and elevated. The balloon is deflated and the catheter is removed, usually...

**Figure 45-15.** Diagram of major arteries close to and underlying the mucosa of the guttural pouch (numbers) and sites of balloon-catheter occlusion (letters). 1, common carotid artery; 2, external carotid artery; 3, internal carotid artery; 4, occipital artery; 5, linguofacial trunk; 6, maxillary artery; 7, caudal auricular artery; 8, 9 superficial temporal artery; 10, transverse facial artery; 11, external ophthalmic artery; 12, caudal alar foramen. A, Balloon inserted in the major palatine artery and guided in retrograde fashion to be inflated immediately caudal to the caudal alar foramen; B, balloon of catheter inserted into transverse facial artery at arrow and directed into the external carotid artery, where it is inflated close to the floor of the guttural pouch; C, balloon in internal carotid artery at the sigmoid flexure, dorsal to the roof of the guttural pouch. This catheter is inserted into the internal carotid artery (3) at the arrow. A, B, C, and arrow on internal carotid artery are also the sites for obstruction with microcoils delivered through a catheter in the common carotid artery (1) in the upper third of the neck. (Redrawn from Caron JP, Fretz PB, Bailey IV, et al: Balloon-tipped catheter arterial occlusion for prevention of hemorrhage caused by guttural pouch mycosis: 13 cases [1982-1985], J Am Vet Assoc 1987;191:345; and Smith KM, Barber SM: Guttural pouch hemorrhage associated with lesions of the maxillary artery in horses, Can Vet J 1984;25:239.)
with considerable traction to get it through the ligature distal to the site of insertion.

**Complications**

Complications associated with this procedure are rare. The catheter rarely penetrates the defect in the artery, and if it does, it can be withdrawn and redirected. Alternatively, the catheter can be left in place to obstruct the hole while another catheter is directed alongside it. This mishap can be detected by intraoperative endoscopy. Infection of the surgical site should be treated by removing the catheter and establishing drainage, and it can be prevented by inflating the balloon to a sufficient diameter (at least 8 mm) to prevent displacement into the infected segment. Delayed prolapse of the catheter through the hole in the artery into the guttural pouch is favored by the normal pressure distal to the balloon and the loss of pressure proximal to it (heart side). The use of the more rigid commercially available catheters can also prevent this complication. Failure to prevent fatal hemorrhage in one case was caused by inadvertent catheterization and occlusion of an aberrant branch from the internal carotid artery, which left the affected segment of artery open to retrograde blood flow. To prevent this mishap, approximately 6 cm of the ICA should be exposed to locate any aberrant branch. Such a branch should be ligated so that the catheter can be maintained in the internal carotid artery.

It may be difficult to distinguish between the occipital and internal carotid arteries in some horses, especially those with a thick throatlatch and those in which both arteries arise as a single trunk and bifurcate at a variable distance from the common carotid artery. If both arteries arise in the normal fashion, the recommended method for identification is to dissect them both free for a couple of centimeters and then elevate each one gently with umbilical tape or a Penrose drain. It should be possible to demonstrate that the internal carotid artery lies deep to the occipital artery and that it courses more rostrally. The most troublesome anatomic aberration is an ICA that leads to the caudal cerebellar artery without following its usual pathway, and that places the inflated balloon in a position that causes neuronal necrosis of the brain stem. If a catheter cannot be inserted to the required distance or passes well beyond the 13-cm mark before it becomes arrested, then it is probably in an aberrant branch.

**Balloon Catheter Occlusion of the External Carotid Artery and Its Branches**

The most likely source of retrograde flow to the external carotid artery and its branches is the major palatine artery, which is a large continuation of the maxillary artery. This joins the contralateral major palatine artery behind the upper row of incisor teeth to form a large arterial loop around the upper jaw. Attempts to occlude the maxillary artery by a single balloon-tipped catheter in the external carotid artery have failed because the catheter tip can readily enter the superficial temporal artery rather than the maxillary artery (see Fig. 45-15). The following procedure was developed to overcome these difficulties.

To prevent normograde flow, the external carotid artery is ligated after the linguofacial trunk and, to reduce retrograde flow, a size 6 French Fogarty venous thrombectomy catheter is inserted into the major palatine artery, 3 cm caudal to the corner incisor tooth. This catheter is inserted retrograde for approximately 40 to 42 cm in a 450-kg horse, or the shortest distance from the arteriotomy to the articular tubercle of the temporal bone. The balloon is partly inflated and the catheter is gently retracted until some resistance is encountered, at which point it is assumed that the balloon is at the articular alar foramen (see Fig. 45-15). It is subsequently fully inflated with sterile saline. At this site, the balloon can obstruct retrograde flow to the maxillary artery (see Fig. 45-15).

As an alternative to ligation, the external carotid artery can be occluded distal to the origin of the linguofacial trunk by a balloon catheter inserted through the transverse facial artery. This obviates the difficulty of exposing the artery through a hyovertrotomy and therefore is most useful in a horse that does not require ligation of the internal carotid artery. The catheter is inserted 3 cm rostral to the articular tubercle of the temporal bone and advanced in retrograde fashion until its tip enters the external carotid artery (approximately 12 cm from the arteriotomy site in a 450-kg horse) (see Fig. 45-15). The balloon is inflated with saline. The redundant ends of catheters in the transverse facial and major palatine arteries are taped to the head or incorporated into a stockinette hood. These catheters are removed after 7 to 10 days without sedation or local anesthesia.

Although the maxillary artery has many collateral branches in the segment between the balloons, this procedure has been effective to date and does not cause blindness, even when combined with occlusion of the internal carotid artery. This difference from ligation of the major palatine artery can be attributed to prevention of the “steal phenomenon” that occurs with ligation. However, the owner should be warned of the risk of blindness.

**Occlusion of the Internal Carotid Artery with Detachable Balloon Catheter Systems**

A detachable, self-sealing, latex balloon can be used to successfully occlude the internal carotid artery, without the need for catheter removal, as required in some cases treated with the nondetachable balloons. Combined with angiography, the detachable system can also be used to occlude aberrant vessels that originate at a distance from the origin of the ICA.

The internal carotid artery is approached as described earlier (see Fig. 45-15), and a 3-cm segment, 1 to 2 cm distal to the origin of the internal carotid artery, is isolated between two Rummel tourniquets of umbilical tape and polyethylene tubing. The balloon delivery system consists of a Tuohy-Borst adapter (Rotating Y Adapter, Medi-Tech, Natick, Mass) that is attached to an 8-F, 95-cm, nontapered, thin-walled guiding catheter (GC 8/95, Laboratoires Nycomed S.A., Paris, France; Yocan Medical Systems, Ontario, Canada). A 2-F, 135-cm, balloon-carrier microcatheter (Mini-Tourquer, CTFN 135, Laboratoires Nycomed; Yocan Medical) is placed through the adapter and guiding catheter, and an 8.5-mm-diameter, detachable, self-sealing,
latex balloon (GoldValve Balloon, GVB 17, Laboratoires
Novomed; Yocan Medical) inflated with 0.5 ml of a 1:1
solution of physiologic saline solution and 66.8% iothala-
mate sodium (Conray 400, Mallinckrodt Medical, Inc, St.
Louis, Mo) is mounted onto the carrier microcatheter.93 The
balloon is then deflated, the carrier microcatheter is
withdrawn so that the balloon is recessed 2 mm inside the
guiding catheter, and the microcatheter is held in place by
tightening the O-ring of the Tuohy-Borst adapter.93

A 19-gauge arterial access needle is inserted into the artery
between the ligatures, and a 0.9-mm (0.035-inch) guide
wire is placed through the needle into the artery.93 The
needle is withdrawn over the wire and an 8-F introducer
sheath (Pinnacle Introducer Sheath, Medi-Tech, Natick,
Mass) is advanced over the wire for 4 cm. The dilator and
wire are removed, and retrograde blood flow from the
cerebral arterial circle is confirmed by bleed-back through
the ancillary fluid port of the introducer sheath. Continuous
infusion of heparinized saline solution (4 U/mL, approxi-
mately 3 mL/min) is then maintained through the intro-
ducer sheath. The balloon delivery system is inserted
through the flexible diaphragm of the introducer sheath and
advanced approximately 13 cm into the internal carotid
artery or until resistance is met. The carrier microcatheter is
advanced 5 to 10 mm within the guiding catheter while the
guiding catheter is retracted 1 cm over the microcatheter.
The balloon is subsequently inflated with 0.5 ml of the
radiopaque solution, and its appropriate positioning and
degree of inflation are confirmed by a single lateral intra-
operative radiograph. The balloon is detached by gentle
traction on the carrier microcatheter, and all proximal
ligatures are secured. All catheters are withdrawn from the
introducer sheath and immediate occlusion of the distal
internal carotid artery is confirmed by lack of retrograde
blood flow through the ancillary fluid port of the introducer
sheath. The introducer sheath is subsequently removed and
the proximal Rummel tourniquet is replaced with two
ligatures of no. 0 polypropylene. The subcutaneous tissues
and skin are closed in layers.

Transarterial Coil Embolization
A transarterial coil embolization technique can selectively
occlude the arterial segments involved in a mycotic lesion in
horses with guttural pouch mycosis.95-98 The coil emboliza-
tion technique combines angiographic studies to image the
affected vessels and identify any unusual vessels and sites of
bleeding, followed by a selective embolization or occlusion
of the affected vessels. Compared with the balloon catheter
technique, transarterial coil embolization allows visualization
of affected vessels throughout the procedure as it is
performed under fluoroscopic guidance.95 This is critical,
because aberrant vasculature has been described in horses
with guttural pouch mycosis, and failure to identify and
occlude such aberrant branches may result in fatal hemor-
rhage.91,99 Also, this procedure eliminates the need to protect
redundant ends of catheters, which is necessary when non-
detachable balloons are used. It is less invasive than the
original balloon catheter procedures and requires shorter
anesthesia and shorter hospitalization. Transarterial embol-
ization can be performed during active bleeding. The surgical

approach for all arteries in the guttural pouch is the
common carotid artery exposed through a single incision.

Under general anesthesia, the horse is placed in lateral
recumbency with the affected side uppermost, and the head
and neck are placed on a radiolucent surface, such as a 30 x
30-cm sheet of Plexiglas, to allow intraoperative fluores-
copy to be performed95 (Fig. 45-16). The fluoroscopy unit must
be mobile and covered with a sterile cover if it is to be
manipulated intraoperatively by the surgeon. All surgical
and anesthesia personnel must wear protective lead aprons
during fluoroscopy (see Fig. 45-16). The proximal aspect of
the jugular groove is clipped and prepared and draped for
aseptic surgery. Drapes must cover the front half of the
horse, as catheters and guide wires used for the procedure
are long and could get contaminated. All catheters, guide
wires, and introducers are flushed with heparinized saline
(10 IU/ml) and left soaking in a bowl containing
heparinized saline until use. A single surgical approach is
sufficient to allow access to all affected branches of the
common carotid artery, such as the ICA, the ECA, the MA,
and aberrant branches (see Fig. 45-16). In general, all
four sites are occluded when lesions are extensive (see Fig.
45-15), or when preoperative hemorrhage precludes
identification of the affected vessel. When the lesion is focal,
only the affected vessel is occluded.

An 8-cm skin incision is made at the junction of the
proximal and middle thirds of the neck, just above the
jugular vein.95 This distal location is important to avoid
exposure of the surgeon’s hands during fluoroscopy (see
Fig. 45-16). The brachiocephalicus and omohyoid muscles
are bluntly separated, and the carotid sheath is elevated
by blunt finger dissection. The vagosympathetic trunk is

Figure 45-16. Room organization for coil embolization techniques.
The horse’s head rests on a thick Plexiglas sheet supported by the
surgery table and a surgery cart so that the fluoroscopy unit can be
positioned more accurately. The fluoroscopy head can be covered
with a sterile drape if the surgeon is to manipulate it into position. The
surgeon is directed by the image on the monitor to guide catheter
advancement. Note the position of the radiation-shielding panels, and
that the surgeon is wearing radiation protection beneath the gown.
The horse’s head is exposed for demonstration purposes but can be
covered with a sterile drape to prevent contamination of the long
catheters.
carefully separated from the carotid artery and replaced within the incision. Care must be taken to prevent tension on the nerves, which could result in postoperative complications such as Horner’s syndrome or laryngeal hemiplegia. The carotid artery is elevated with umbilical tape and is punctured with an angiographic needle. A 6-F introducer system (Cook Inc, Bloomington, Ind) is inserted into the artery and guided toward the head (Fig. 45-17). The correct position of the introducer is verified by injection of contrast material before proceeding. Misdirection into the cranial thyroid artery precludes advancement of the angiography catheter and requires that the introducer be slightly withdrawn and repositioned into the CCA under fluoroscopic guidance. A 6-F single-end-hole nylon angiographic catheter (Cook Inc) is advanced rostrally into the common carotid artery to the level of the ICA under fluoroscopic guidance.

Coils pass less readily through polyvinylchloride or vinyl catheters, so these should not be used. Angiography is performed during catheter advancement by hand-injection of 3 to 5 mL of a 1:2 solution of iohexol in heparinized saline, or iodinated contrast material, to identify the path of each vessel. All injections are made using a double-flush technique through a three-way stopcock. To avoid embolization of thrombi that may have formed within the catheter, heparinized saline is flushed and aspirated before injection of contrast material. Injection of air must be avoided by carefully expelling air from all syringes, and by performing injections with the piston of the syringes directed upward.

Preembolization angiography is mandatory for anatomic identification and location of the vessels, exclusion of vascular anomalies, abnormal vascular connections between the ICA and the occipital artery, and correct positioning of the embolization coils. Small or aberrant arterial branches are present in up to one third of horses and require selective embolization. If a connection is present between two embolization sites, continued bleeding could still occur, and therefore such small branches must be occluded separately. The distal (cerebral) side of the lesion in the ICA is embolized first, to protect the cerebral circulation from any intraoperative errors such as air or clot embolization. The distal ICA is embolized at the level of its superimposition on the basisphenoid bone and caudal to the sigmoid flexure. To select a coil diameter, an estimate of the width of the artery at the embolization site is made by using the known diameter (3 mm) of the angiography catheter as a guide. For the distal ICA coil, diameters of 5 to 8 mm are usually necessary, although 3 mm may be needed in smaller horses or ponies. A Dacron fiber–covered, stainless steel, occluding spring embolization coil (Emb olization Coils, Cook Inc) of proper diameter is introduced through the catheter, while its tip is in the desired location, and pushed into the ICA by the stiff end of a guide wire (Fig. 45-18). A coil slightly larger than the artery is placed first, and additional smaller imbricating embolization coils follow until complete occlusion is obtained. To imbricate the coils, the tip of the catheter is placed within the previous coil.

After occlusion is verified by injection of contrast material, the proximal (cardiac) side of the ICA is embolized next, midway between the first embolization site and its origin from the common carotid artery (Fig. 45-19). After occlusion of the ICA, the catheter is withdrawn into the common carotid artery and advanced to repeat the same procedure in the caudal MA and rostral ECA. The MA is embolized distal to the superficial temporal and proximal to the infraorbital, buccal, and mandibular alveolar arteries. Verification of correct identification of the maxillary artery is made by inserting the catheter further and imaging the ophthalmic artery. The catheter is subsequently withdrawn until it is within the alar foramen, just distal to the curvature of the maxillary artery, and cranial to the most cranial aspect of the guttural pouch outline. Coils of 8 to 12 mm in diameter are necessary at this location. The ECA is embolized next, on the caudal (cardiac) side of the origin of the caudal auricular artery. The ECA requires the largest size and greatest number of coils to achieve immediate and complete occlusion, usually 10 to 15 mm diameter.

After coil placement, the catheter and introducer system are removed. The common carotid artery puncture site is closed using 5-0 silk in a cruciate pattern, and the muscle layers and skin are closed in three layers. Phenylbutazone is administered for 3 to 5 days after surgery to minimize inflammation.

**Figure 45-17.** The carotid artery is elevated with umbilical tape and is punctured with an angiographic needle. A 6-F introducer system (Cook Inc, Bloomington, Ind) is inserted into the artery and guided toward the head.

**Figure 45-18.** Microcoil used for coil embolization. The coils are made of stainless steel coated with Dacron fibers and presented in a stainless steel sheath. Coil formation is achieved by pushing the guide wire into the sheath (right) to deliver the coil (left) at the desired location.
inflammation at the incision site. Horses are rested for 30 days and then gradually returned to use. This technique has been successful in 27 of 28 horses affected with guttural pouch mycosis, and the single failure was caused by unidentified abnormal anatomy and aberrant branching that resulted in continued hemorrhage. Such atypical anatomy may be more common than reported with this disease, so preocclusion angiography is critical. The ability to selectively occlude affected vessels with a minimally invasive approach makes transarterial coil embolization the preferred treatment.

The disadvantages of this technique are the need for fluoroscopy (and the specialized equipment and expertise involved), positioning of the horse’s head for fluoroscopy, and radiation-shielding apparel and equipment. Although these disadvantages would limit this technique to a small number of well equipped hospitals, coils have been implanted in the internal carotid artery using a cut-down procedure similar to that for the balloon catheters. Placement can be determined as for balloon catheters and confirmed by lack of back-flow through the arteriotomy and assessment of coil placement by radiography. The same approach has been described with an allowance of 10 minutes after coil placement for a clot to form, followed by an injection of contrast material at 200 mm Hg for 3 seconds to determine occlusion. This direct approach to the ICA also obviates the need for a proximal coil occlusion, because a ligature at the site of catheter insertion will prevent normograde flow. The major disadvantages of the cut-down procedure are failure to identify unusual anatomy and aberrant connections and to precisely position the microcoils.

ANATOMY AND PHYSIOLOGY

The equine trachea is a membranous and cartilaginous tube extending from the larynx at the level of the 1st or 2nd cervical vertebra to the level of the 5th or 6th intercostal space, where it bifurcates into the principal bronchi dorsal to the base of the heart.1 The trachea is median in position except for its very terminal thoracic part, where it is pushed to the right by the aortic arch. From just caudal to the larynx to its bifurcation, the equine trachea is about 70 to 80 cm long.

When operating on the trachea, its relationship to other structures is important. The arrangement of the muscles
The wall of the trachea can be divided into four layers: mucosa, submucosa, the musculocartilaginous layer, and the adventitia. The adventitia is a connective tissue layer that blends with the musculocutaneous layer and with the connective tissue surrounding the trachea. It is composed of loose areolar tissue that allows a considerable amount of movement of the trachea along its length. The musculo-cartilaginous layer consists of the cartilaginous plates, fibroelastic tissue (annular ligaments), and the tracheal muscle. The cartilaginous plates number between 48 and 52. These cartilaginous plates are curved within the cartilaginous plates and become obvious when they are traumatized or when incisions are made into the tracheal rings. Preventing and managing complications of tracheal surgery requires an understanding of the anatomy and physiology of the trachea. The evaluation should also include manual palpation of the trachea.
of powder insufflation provides a safe and accurate means of evaluating bronchial conditions in the horse. This could have some application toward tracheal disease.

CONDITIONS REQUIRING TRACHEAL SURGERY

Rostral Upper Airway Obstruction
Surgery of the trachea is often an emergency procedure to bypass a life-threatening obstruction of the upper respiratory tract. It may also be conducted as a route for endotracheal intubation for general anesthesia when routine nasotracheal or orotracheal intubation limits access to the surgical field. Additionally, surgical interventions are performed to physically rest the upper respiratory tract on a temporary basis, or to simply bypass an inoperable upper respiratory tract obstruction (such as bilateral arytenoid chondritis).

Tracheotomy
Temporary tracheotomy and tracheotomy with an indwelling tracheal cannula (tracheostomy) may be performed with the horse standing or under general anesthesia. In the standing horse, the ventral midline of the neck is easier to locate (with regard to all tissue layers) and the dissection of the trachea is easier than in the anesthetized horse in dorsal or lateral recumbency, because the trachea shifts within the neck if the neck is not held in a perfectly vertical position. Tracheotomy is performed at the junction of the upper and middle thirds of the neck. The trachea is located superficially at this level. The horse is sedated in the stocks and the surgical site is prepared for aseptic intervention. Local anesthetic is injected on the ventral midline under the skin and into the paired sternothyrohyoid muscles prior to incision.

If the surgery is to be performed in the recumbent animal, a pad is placed under the head to place the neck in a slightly flexed position after the neck and the trachea have been placed in vertical position and as straight as possible. The objective is to align the skin so that it is in the position it will be after the horse recovers and is standing normally.

With the horse standing or in recumbency, a 10-cm incision is made through the skin, subcutaneous tissue, and cutaneous colli muscle. The paired sternothyrohyoid muscle bellies are bluntly divided along the ventral midline for a distance of about 8 cm and held in a retracted position with a self-retaining retractor (Fig. 46-1). The cartilage of the trachea can then be easily palpated. Although vertical and flap procedures are used in dogs, only the transverse tracheotomy technique is used in the horse to prevent problems with tracheal collapse and granulation tissue formation. Therefore, the annular ligament between two adjacent cartilage rings is incised parallel to the orientation of the rings. The incision between the rings is lengthened to allow placement of a tracheal cannula. The incision should not exceed one half the circumference of the trachea. A large hemostatic forceps or an index finger may be inserted between the rings to guide the tracheal tube in the lumen.

A variety of tracheal tubes are manufactured. Self-retaining tubes are popular because they do not require skin sutures for security. Short-cuff silicone tubes are a good choice (Fig. 46-2), because their compliance makes them more comfortable than rigid metal tubes. However, the cuff should not be inflated if the tubes are used long term, as they will produce mucosal erosions. Therefore, they are usually tied in place using the flanges on either side of the tubes.

Figure 46-1. After the paired sternothyrohyoid muscles are bluntly divided along the ventral midline, they can be held in place with Weitlaner or baby Balfour retractors as shown. This provides good exposure to multiple tracheal rings.

Figure 46-2. A short-cuff tracheal tube made out of silicone. The flanges are used to tie the tube in place.
removed may provide an airway until a better option is available. In an emergency situation, tracheotomy is difficult when performed on a horse that is struggling because of airway obstruction. It may be necessary to allow the horse to collapse; however, from that point forward, speed is imperative because the horse can die shortly after this stage is reached. The tracheotomy site should be cleaned and the indwelling cannula should be removed twice daily to remove accumulated tracheal secretions that could cause airway obstruction.

When direct tracheal intubation through a tracheotomy is carried out to avoid orotracheal or nasotracheal intubation, the procedure can be accomplished in the standing sedated or recumbent anesthetized horse. Precautions are taken to ensure that the skin incision is made on the ventral midline in the recumbent horse, because inappropriate positioning may create excessive skin tension or stoma obstruction at the tracheotomy site on recovery. The endotracheal tube should not extend past the carina, since endobronchial intubation will impair ventilation.

**COMPLICATIONS**

Early complications can be reduced by using aseptic technique and by performing minimal soft tissue dissection to limit the amount of dead space. Complications after aseptic tube placement are uncommon. Occasionally, the wound becomes infected or the horse develops subcutaneous emphysema. More commonly, obstruction of the tracheal cannula with mucous secretions occurs and needs clearing. This problem should be closely monitored and the tube replaced at least every 24 hours. Occasionally, the tracheal cannula is inadvertently placed peritracheally because of the loose areolar tissue around the trachea. This can be recognized immediately by the lack of air movement through the tube while the horse is breathing.

Long-term complications, including damage to tracheal cartilage or intraluminal granulation tissue and mucosal stricture, are extremely rare. Attention to the soft tissue dissection and aseptic technique whenever possible reduces these complications. Removal of the endotracheal cannula as soon as possible also reduces long-term complications. After the cannula is removed, the wound is left to heal by second intention with daily cleansing.

**Tracheostomy**

Permanent tracheostomy is used for correction of permanent impairment of the laryngotracheal apparatus such as bilateral laryngeal hemiplegia or chondritis. Permanent tracheostomy has been used to provide a large, stable, permanent tracheal stoma with minimal complications. A retrospective study that followed 42 horses for an average of 4.8 years found that stomas remained functional and 91% of owners would have it done again. The author has had good success with long-term function of tracheal stomas created in a number of adult horses.

Permanent tracheostomy can be performed with the horse sedated and standing or anesthetized and positioned in dorsal recumbency. The procedure should be performed under general anesthesia until the surgeon is comfortable with it before it is attempted in the standing horse.

**SURGICAL TECHNIQUE WITH GENERAL ANESTHESIA**

The horse is anesthetized and positioned in dorsal recumbency with the ventral cervical area prepared for surgery. A 10-cm ventral midline incision is made through the skin, subcutaneous tissues, and cutaneous colli muscle in the cranial third of the cervical region just caudal to the larynx (Fig. 46-3). The paired sternothyrohyoideus muscles are

![Figure 46-3. Surgical technique for permanent tracheotomy. A, Exposure of tracheal cartilage rings after separation of the sternothyrohyoideus muscles. B, Incision of tracheal cartilages. C, Removal of eight tracheal cartilage rectangles. D, Line of incision of tracheal mucosa and placement points for stay sutures (circles). E, Mucosal epidermal apposition.](image-url)
separated and retracted laterally to expose four tracheal rings. (The most cosmetic appearance is achieved if tracheal rings two to five are removed.) A 3-cm-wide band of each of these muscles is bluntly separated and transected on either side of the midline so that the skin will lie easily on the trachea without tension. The area is packed with gauze sponges to stem the bleeding as the rest of the surgery progresses. A ventral midline incision and two paramedian incisions 15 mm on either side of the midline are made through the tracheal cartilages without disrupting the tracheal mucosa underneath. The rectangular cartilage pieces are carefully dissected from the tracheal submucosa and removed. The tracheal mucosa and annular tracheal ligaments are incised in a double-Y pattern and stay sutures used to maintain mucosal traction. The intersection of the legs of each Y in the mucosa are elevated and sutured to the skin with 2-0 polypropylene in a simple-interrupted pattern. The main tracheal mucosa is apposed to the skin lateral to the stoma in a similar manner.

The stoma is cleaned twice daily until the sutures are removed and then once daily afterward. The sutures can be removed 10 to 14 days after surgery; however, by that time many of the sutures have sloughed and with time all of them will be extruded if they cannot be easily removed. This technique provides a cosmetically acceptable, structurally sound stoma, needing minimal aftercare (Fig. 46-4). The stoma is unlikely to be obstructed by accumulated secretions, even if daily cleaning is not done.

The stoma can be located at any site in the proximal third of the neck. However, for best cosmetic results, this stoma can be located beginning at the second tracheal ring. This often provides a permanent stoma that is not easily recognizable to the untrained observer. It is not recommended that the first tracheal ring be removed.

SURGICAL TECHNIQUE IN THE STANDING HORSE

If permanent tracheostomy is performed with the horse sedated and standing, the horse is restrained in stocks and cross-tied with the head extended. The horse is sedated and a local anesthetic infiltrated subcutaneously in an inverted-U pattern dorsal and lateral to the second through the fifth tracheal rings. The 6-cm-long incision is made through the skin centered over the ventral midline beginning 3 cm distal to the cricoid cartilage. The paired sternothyrohyoid muscles are isolated and removed as previously described. The tracheal mucosa is then desensitized by injecting 30 mL of 2% lidocaine with a 1-inch, 23-gauge needle into the lumen of the trachea proximal to the surgery site. The ventral third of the second through the fifth tracheal rings is resected as previously described, leaving the tracheal mucosa intact. The longitudinal double-Y incision is subsequently made through the tracheal mucosa and annular tracheal ligaments, and the stoma is completed by suturing the tracheal mucosa and the submucosa to the skin with simple-interrupted sutures of no. 0 polypropylene in the simple-interrupted pattern.

COMPLICATIONS

Although the permanent stoma affects pulmonary defense mechanisms by reduced airway temperature control and altered humidification of inspired gases, the mucosal ciliary escalator continues to work, and mucus is continuously extruded through the stoma. Horses with existing pulmonary disease may have exacerbation of chronic pulmonary disease, or signs of respiratory disease may be induced, but this has not been the author’s clinical experience.

Tracheal collapse will occur postoperatively if care is not taken to ensure that segments of the cartilage are removed from the ventral third of the cartilage rings only, and not close to the trachealis muscle. In older animals, the tracheal ring may become twisted, and if that is the case removing the center third of the cartilage ring is important even if it is off center. The amount of tension that is experienced from the skin can be adjusted by removing more of the sternothyrohyoid muscle if necessary. Also, to avoid tracheal collapse, no more than one third of the entire circumference of the ring should be removed.

Tracheal Perforation or Rupture

Disruption of the integrity of the tracheal lumen is usually caused by trauma. Clinical signs of tracheal trauma depend on the site of the tracheal injury, but trauma can cause tracheal perforation without concurrent cartilage damage or obvious skin damage or even rupture of the annular ligament (Fig. 46-5). Clinical signs include subcutaneous emphysema and harsh tracheal sounds. Often, the perforation or disruption is not recognized until regional subcutaneous emphysema develops. When these signs occur in mares separated from their foals by wire fences at weaning, tracheal trauma should be suspected. The subcutaneous swelling is usually nonpainful, soft, easily indented, mobile, and crepitant. When tracheal trauma is suspected, thoracic radiographs should be taken to check for pneumomedastinum. Continued leakage into the mediastinum may lead to pneumothorax. Small tissue perforations in the absence of cartilage damage may not be apparent on radiographs, but both large and small lesions are usually apparent with tracheoscopy (Fig. 46-6). Although the small tears rapidly form a fibrin seal, large ruptures should be treated promptly to avoid infection, obstruction from peritracheal tissue, progression of subcutaneous emphysema to the mediastinum, and development of pneumothorax. Small defects may respond to a pressure bandage over the affected region, which reduces the subcutaneous emphysema.

Figure 46-4. Permanent tracheostomy provides a cosmetically acceptable, structurally sound stoma requiring minimal aftercare.
Although small tears can be managed conservatively and generally resolve within 24 to 48 hours, the large tears should be managed surgically as soon as the horse’s condition allows such an intervention. If there is a wound, the tears in the cervical trachea can be approached and directly sutured after débridement of devitalized tissue. Wound margins are apposed in a simple-interrupted pattern of no. 0 absorbable suture material. Injuries that involve the trachealis muscle or the adventitia of the trachea, or that are rotational in nature, can be repaired by rotating the trachea to expose the dorsal surface. Closed suction drains are recommended in the postoperative period and should be removed every 48 to 72 hours, depending on the appearance of the wound and the amount of drainage. Once the tracheal defect is closed, the subcutaneous emphysema usually resolves in 7 to 10 days.

Resection and Anastomosis

When tracheal trauma is extensive or when complete rupture occurs between tracheal rings, tracheal resection and anastomosis is indicated. Before attempting a tracheal resection and anastomosis, the horse must be trained to wear a Martingale-type harness, which restricts dorsal movement of the head and reduces tension at the anastomotic site. This is particularly important if sections or rings need to be removed. If sections or rings do not need to be removed and the harness is quickly tolerated, the surgical preparation can occur immediately. Broad-spectrum antibiotics are administered prophylactically and the horse is anesthetized and positioned in dorsal recumbency.

The ventral cervical midline is prepared for aseptic surgery. A ventral midline cervical incision is made through the skin, subcutaneous tissue, and subcutaneous colli muscles over a distance of about 40 cm centered over the affected area. The sternothyrohyoid muscles are divided to expose the trachea. The trachea is separated from adjacent tissues along the entire cervical region within the incision site. If cartilage rings are to be removed, stay sutures are placed in tracheal cartilages adjacent to the segment to be removed. Up to five cartilages can be removed; however, tension on the anastomotic site will be excessive, and as few cartilages as possible should be removed (Fig. 46-7). Tracheal mucosa and annular ligament are incised to divide the trachea into proximal and distal segments. The endotracheal tube is removed and replaced in the distal segment. The tracheal mucosa is turned back over the open ends of the proximal tracheal segment and sutured to the adventitia. The same procedure is repeated on the distal segment, working around the endotracheal tube. The head is subsequently flexed at a right angle with the neck. The endotracheal tube is replaced through the mouth and advanced into the distal segment of the trachea. If this is not possible because of the distal location of the injury, the endotracheal tube needs to be placed through another tracheotomy incision proximal to the anastomotic site. Tracheal ends are apposed with towel clamps and anastomosed with 25-gauge stainless steel wire in a simple-interrupted pattern without mucosal penetration. After the anastomosis is complete, it is checked for air leaks prior to completely withdrawing the endotracheal tube. A continuous suction drain is placed in the soft tissue, and the remaining tissue layers are closed. The harness is applied before recovery and left in place for 3 weeks. Antibiotics are usually continued for 5 days. Complications include breakdown of the anastomosis and infection. Fistulation around the steel sutures persists if infection is present and development of intraluminal abscesses in the anastomotic site is possible. Therefore, these sutures may need to be removed if abscesses develop after the trachea is healed.

Tracheal Collapse

Tracheal collapse can be a sequela to peritracheal abscesses, tumors, any injury causing cartilage trauma, malformation of the cartilages, or chronic pneumonia. An idiopathic primary collapse syndrome has also been reported in the horse. Primary tracheal collapse is recognized by widespread or segmental dorsoventral flattening of tracheal cartilage rings. Neurologic, congenital, or nutritional
abnormalities may cause collapse in other species. Tracheal collapse uncomplicated by trauma is reported only in mature horses. It also occurs after emergency tracheotomy when vertical incisions were made through the rings. When tracheal collapse occurs from dorsoventral flattening of the trachea in aged horses and particularly ponies, the tracheal rings form shallow arcs and the dorsal tracheal membrane is stretched, creating an elliptical rather than a circular cross-section.

Clinical signs vary with the degree of tracheal obstruction. Most animals experience varying degrees of respiratory distress and exercise intolerance and usually exhibit some stridor, although some animals may be asymptomatic until they become stressed. Diagnosis can be confirmed by auscultation, palpation, endoscopy, and radiography. Turbulent airflow may be auscultated within the cervical trachea and may thus allow localization of the site. Palpation may reveal the lateral edges of flattened tracheal rings in the jugular groove. Endoscopy will show the abnormal shape of the tracheal lumen, and lateral radiographs will depict the narrowed tracheal outline.

Treatment of tracheal collapse depends on the etiologic factors, length of the trachea involved, and accessibility of the affected area. Tracheal reconstruction has included complete replacement of tracheal segments with prostheses, external prostheses, imbrication of collapsed tracheal rings, plication of the trachealis muscle to reduce laxity of that structure, and resection of damaged cartilages with anastomosis of unaffected tracheal regions. The primary goal of the surgery is to restore the tracheal diameter without affecting the mucosal ciliary apparatus. This is best accomplished with an extraluminal prosthetic device that restores tracheal diameter by limiting redundant dorsal tracheal membrane and providing rigid support for the tracheal wall. Polyethylene syringe cases have commonly been used in ponies, but any nonreactive material of similar shape could be used. Partial chondrotomy is usually required on the ventral aspect of each collapsed tracheal ring to correct some deformities, which occur when this dorsoventral flattening has occurred over time. Failure of the prosthesis to work will result in resection and anastomosis as a second choice; however, no more than five rings can be removed, and frequently dorsoventral collapse of a chronic nature involves more rings than this.

**Tracheal Stenosis**

Tracheal stenosis refers to a narrowing or stricture of the tracheal lumen that can occur during healing of a tracheotomy made by transverse incision through more than 50% of the circumference of the annular tracheal ligament (Fig. 46-8). This produces instability and abnormal scarring. Other causes, particularly in foals, include Streptococcus equi abscesses in the peritracheal mediastinal lymph nodes and trauma. Tumors occur in this region, but tracheal collapse and stenosis secondary to tumors are unusual. Prolonged endotracheal intubation is associated with mucosal hemorrhage, necrosis, and stricture in people, and these lesions are frequently treated with surgery for removal of the circumferential fibrous tracheal stenosis. Additionally, penetrating wounds that disrupt the tracheal mucosa, with or without infection, may lead to the development of tracheal stenosis.

Surgical procedures used in the treatment of tracheal stenosis include tracheal resection and anastomosis, extraluminal polypropylene prostheses, surgical drainage of peritracheal abscesses, and multiple tracheal ring chondrotomies with placement of retention sutures anchored to the skin.
Foreign Body

Tracheal foreign bodies are uncommon in mature horses because of the size of the lumen of the trachea; however, endobronchial foreign bodies, although rare as well, are reported in equine patients. They usually contain plant material, which may be inhaled accidentally, particularly during food prehension. The removal of foreign bodies from the respiratory tract is usually accomplished under general anesthesia and by way of tracheotomy. Frequently, removal involves endoscopic retrieval or endoscopically assisted surgical techniques. Foreign bodies in the tracheobronchial tree usually have thorns, which cause them to lodge in the bronchi. The clinical signs usually include coughing and epistaxis, and a bloody nasal discharge is not uncommon. Usually, despite the severity of bronchial lesions, improvement in the bronchial mucosa is observed very soon after removal of the plant material, and few long-term effects are reported.

Granulomas

Granulomatous nodules are occasionally observed in the trachea during endoscopic examination. Often these are in the proximal trachea near the larynx, but occasionally they are associated with healing tracheotomy incisions, foreign body irritation, or inappropriate passage of a stomach tube that damages the tracheal mucosa. Although they are usually an incidental finding and not associated with clinical signs, if they are of sufficient size to create airflow obstruction they can be removed using an endoscopically guided laser technique.

REFERENCES

Thoracic disorders in horses amenable to surgical intervention include pleuropneumonia and pleural effusion (see Chapter 48), infectious or neoplastic masses, and thoracic trauma. This chapter’s emphasis is on thoracic trauma and associated disorders, with some discussion on thoracic masses. Thoracic injuries in horses occur as a result of blunt or penetrating trauma. Blunt trauma is commonly seen in neonatal foals and believed to result from excessive compression of the pelvic canal of the dam during parturition. In adult horses, penetrating trauma caused by collision with an object is most common. Conditions associated with thoracic injuries include pneumothorax, hemothorax, rib fractures, flail chest, pulmonary contusion or laceration, and diaphragmatic hernias, and these can occur alone or in combination.

The pathophysiology of respiratory distress in horses with thoracic injury is complex. Pain associated with thoracic trauma restricts full expansion of the thorax during inspiration. This can induce rapid, shallow breathing, hypoventilation, and decreased clearance of pulmonary secretions that can eventually result in hypoxia and hypercapnia. Pneumothorax, hemothorax, and contusion of pulmonary parenchyma can develop secondary to injury and can also contribute to respiratory insufficiency. Evaluation of a horse presented for thoracic trauma must be thorough but rapid, and, if necessary, potentially life-threatening conditions must be identified and immediately addressed. Emergency management of thoracic trauma patients (see Chapter 8) is directed at providing respiratory support to restore adequate ventilation and oxygenation, analgesia, and treatment of hypovolemic shock.

### CLINICAL PRESENTATION

Horses with thoracic injuries may be presented with a range of signs, from stiffness at the walk or anxiety resulting from thoracic pain, to severe respiratory distress. Clinical signs of respiratory distress include excessive respiratory effort, nostril flaring, tachypnea, dyspnea, accentuated thoracic excursion, and cyanotic mucous membranes. Clinical signs may be subtle or dramatic, specific or nonspecific, and immediate or delayed in onset. This is especially true in horses with axillary wounds. Initial evaluation of the respiratory system should include observation of the thoracic excursions, auscultation and palpation of the trachea and thorax, thoracic radiographs, thoracic ultrasonography, and arterial blood gas analysis.

### DIAGNOSIS

#### Physical Examination and Triage

The physical examination of a horse with thoracic trauma should be both thorough and systematic. Observation of the rate, depth, and effort of respiration may help the clinician identify specific conditions. Rapidly developing respiratory distress is generally the result of pneumothorax or severe pulmonary contusion. Horses with hemothorax and pneumothorax develop a rapid and shallow respiratory pattern because of the restriction of lung expansion caused by the presence of fluid or air in the pleural cavity. A similar pattern of respiration can occur in horses with thoracic wounds or rib fractures, and this is most likely the result of restriction of thoracic wall movements because of pain. Paradoxical movement of the thoracic wall can be observed and is caused by collapse of a portion of the rib cage on inspiration when multiple rib fractures create an unstable flail chest wall.

Palpation of the thoracic wall should be performed to evaluate the potential presence of subcutaneous emphysema (crepitus), fractured ribs, hematomas, and unstable (flail) segments. Localized crepitus with or without a hematoma suggests the presence of fractured ribs, whereas more diffuse subcutaneous emphysema may indicate the presence of pneumothorax, pneumomediastinum, or axillary wounds. Thoracic auscultation and percussion help determine the presence of pneumothorax and hemothorax. The absence of respiratory sounds and increased resonance on percussion strongly suggest pneumothorax. However, auscultation of the thorax should not be relied on as the sole means of diagnosing pneumothorax in horses. In a retrospective study, only 55% of the horses diagnosed with pneumothorax had decreased lung sounds dorsally. When fluid accumulates in the pleural cavity, with hemothorax, lung sounds are diminished ventrally, heart sounds resonate over a larger area, and a fluid line can be detected on percussion of the ventral thorax. If crackling lung sounds are heard, pulmonary contusions should be suspected.

Several additional parameters should be monitored during the initial examination. The hematocrit and plasma total solids should be assessed at presentation and periodically afterward to determine if there is ongoing hemorrhage. Moreover, arterial blood gas analysis can help determine ventilatory function and the ability to oxygenate the tissues. If arterial blood cannot be obtained, a venous sample can allow assessment of ventilation. Hypoventilation is present if the PCO₂ is greater than 50 mm Hg, and hypoxemia is identified by an arterial PO₂ of less than 80 mm Hg. Frequent blood gas analyses can help assess if a horse’s respiratory system is deteriorating or responding favorably to treatment.

Horses with thoracic trauma may suffer concurrent abdominal injury because of the close proximity of the abdomen to the thorax. Evaluation of the abdominal cavity is especially indicated when lacerations are present caudal to the 6th rib or when a deep penetration is suspected. Abdominoceelectasis, ultrasonography, laparoscopy, or exploratory celiotomy can be used to rule out visceral involvement or rupture. Musculoskeletal injuries can also accompany thoracic trauma, but they are typically of secondary importance to systemic stabilization.
Radiography and Ultrasonography

Radiography and ultrasonography are valuable diagnostic tools for evaluation of the equine thorax. Pneumothorax is evident radiographically by the separation of the lung margins from the diaphragm caudally and the vertebral bodies dorsally, thus allowing the pleural surface of the collapsed lung to be observed (Fig. 47-1). Pneumomediastinum is diagnosed by the presence of air that outlines the mediastinal contents, and it can coexist with pneumothorax, usually secondary to trauma. Radiographs can also reveal other lesions, such as rib fractures, foreign objects, and diaphragmatic hernias. Intrathoracic and pulmonary masses may be seen as areas of increased soft tissue opacity that summate with or displace structures in the mediastinum, lung tissue, or thorax. Primary lung tumors tend to be well circumscribed and solitary. On the other hand, metastatic neoplasia is typically noted as multiple circular opacities of varying size and shape.

Thoracic ultrasonography is more valuable than radiography for confirming the presence of pleural fluid and for determining the best site for thoracentesis or placement of indwelling chest tubes. Ultrasonographic examination may permit the identification of foreign material, masses in the pulmonary parenchyma and cranial mediastinum, rib fractures, and diaphragmatic hernias. Pneumothorax may be difficult to diagnose because free air in the dorsal thorax and aerated ventral lung lobes appear ultrasonographically similar. Thoracentesis can be performed to obtain a sample of pleural fluid for analysis or to drain air or fluid from the pleural space. Aspirated fluid should be submitted for cytology studies, aerobic and anaerobic cultures, and antibiotic sensitivity testing. Sensitivity testing is important when hemothorax is caused by penetrating wounds, as the risk of contamination and subsequent infection is great.

Thoracoscopy

Equine thoracoscopy can be used to provide a more accurate diagnosis and prognosis of thoracic diseases when less invasive diagnostic tools fail to yield an accurate assessment. Common uses of thoracoscopy include the following14-16:

1. Exploration of the thorax of horses with suspected neoplasia or pleural effusion of unknown origin
2. Drain placement for relief of pleural effusion and abscesses
3. Transection of pleural adhesions
4. Pulmonary biopsy
5. Window pericardectomy

In addition, thoroscopic surgery has been used to diagnose and assist in the repair of diaphragmatic hernias, and for exploration of the thorax in horses with open penetrating wounds.17,18 Additional information on thoracoscopy can be found in Chapter 14.

Thoracoscopy can be performed with the horse standing or under general anesthesia. Thoracoscopy in the standing horse has proven to be safe, well tolerated, and associated with minimal detrimental effects to the cardiovascular and pulmonary function of healthy horses and horses with chronic lung disease.19,20 The presence of a pneumothorax during thoracoscopy can cause a transient hypoxemia attributed to ventilation/perfusion mismatch and a slight decrease in cardiac output secondary to decreased venous return.20,21 Analysis of arterial blood gases is considered essential to evaluate ventilation and oxygen exchange, especially in horses with compromised lung function.

For thoracoscopy in standing horses, the animal is restrained in stocks and sedated with xylazine (Rompun, Bayer Corporation, Shawnee, Mich.) at 0.5 to 1.1 mg/kg IV, with detomidine (Dormosedan, Pfizer Animal Health, West Chester, Pa) at 8 to 10 µg/kg, or by use of a continuous IV drip infusion of detomidine (an 8-µg/kg loading dose followed by an administration rate of 0.3 to 0.5 µg/kg per minute until the desired effect is observed). During surgery, analgesia is provided by a single bolus of butorphanol tartrate (Torbugesic, Fort Dodge Laboratories, Fort Dodge, Iowa) (0.04 mg/kg IV) and local anesthesia of the skin, subcutaneous tissue, intercostal musculature, and costal pleura at each incision site. The thoracic chest wall is clipped and prepared for aseptic surgery. The sites for the telescope and instrument portals depend on the surgical intervention. The thoracic cavity can be better evaluated when the telescope is introduced into the thorax just cranial to the 10th to 12th intercostal spaces, avoiding the vessels and nerves located caudal to the ribs.22 The mobility of the ribs at this location allows manipulation of the telescope for extensive exploration of the thorax. Selection of a thoracoscopic portal caudal to the 15th intercostal space can result in inadvertent injury of the diaphragm during insertion of the trocar-cannula system.20 On the other hand, placing portals too far cranial at the eighth intercostal space causes some pain and discomfort during manipulation of the instruments or telescope as a result of distraction of the ribs.22 A 1-cm stab incision should be made through skin and intercostal muscles just ventral to the epaxial muscles. To prevent damage to the lung by the trocar–cannula system through which the thoracoscope is inserted, a pneumothorax is induced by inserting a teat cannula into the thoracic cavity through the incision and the intercostal muscles into the pleural cavity.

Figure 47-1. Thoracic radiograph of a horse with a rib fracture (arrow) that resulted in pneumothorax, as evidenced by air within the chest (appears black). The collapsed lung (L) lies ventral to the accumulated air.
After the pneumothorax is induced, the teat cannula is replaced by the trochar/cannula system. The trocar is then removed and replaced by the telescope. Once the telescope is inserted, a systemic exploration is performed and the desired surgical intervention is performed using triangulation technique. Multiple instrument portals are placed at least 10 to 15 cm apart (two to three intercostal spaces) to avoid obstruction of vision or restriction of instrument manipulations. Thorascopic viewing of the surgical field prevents injuries to thoracic structures during insertion of instrument and trocars. At the conclusion of the procedure, the thoracic cavity is inspected one final time and thoracic negative pressure is reestablished by removing all the air from the pleural cavity through a suction system connected to the thorascopic cannula. Lung reinflation is observed through the telescope, which is retracted to the distal end of the endoscopic cannula, as inflation occurs. The telescope is removed and skin over the portals is closed with nonabsorbable suture material.

Thorascoscopy under general anesthesia is performed with the horse in either lateral or dorsal recumbency. To perform the procedure under general anesthesia, positive-pressure ventilation is an absolute necessity, because bilateral pneumothorax is more common in the anesthetized than in the standing horse during thorascoscopy. After surgical preparation of the ventral aspect of the thorax, a pneumothorax is induced as previously described, and the telescope and instrument portals are made as dictated by the surgical intervention. On some occasions, CO₂ insufflation of the pleural cavity is utilized to facilitate surgical exposure. However, intrapleural pressure greater than 3 to 4 mm Hg can result in cardiovascular and pulmonary deterioration. Thorascoscopy under general anesthesia improves the viewing of the ventral lung surfaces, ventral thoracic cavities, diaphragmatic surfaces, and lateral surface of the heart.

Thorascopically guided lung biopsy has been described as safe and successful in the harvest of tissue samples for histologic and microbiologic examination. Pulmonary tissue samples are collected from the caudodorsal aspect of the lung, because when lung disease is diffuse, this site appears to be representative of the remainder of the horse’s lung. Direct observation of the surgical biopsy and excellent hemostasis enable surgeons to avoid complications reported by others when performing percutaneous lung biopsies. Furthermore, multiple resections can be performed or larger wedge resections can be obtained when necessary. The main disadvantage of this technique is that the tissue access is limited to the periphery of the lung and therefore samples are useful only for peripheral lesions or diffuse interstitial diseases. If pulmonary lesions are seen during thorascoscopy on the broad surface of the lung, a biopsy can be performed with fine-needle aspirates, endoscopic biopsy forceps, or other biopsy instruments.

Thorascopically guided lung biopsy is performed with the horse standing under chemical restraint. The telescope portal is placed at the 12th or 13th intercostal space. One instrument portal is placed one or two intercostal spaces cranial and 15 cm ventral to the telescope, and the other instrument portal is located at the 15th intercostal space and approximately 10 cm ventral to the telescope portal. The caudal aspect of the caudal lung lobe can be grasped with atraumatic forceps (Babcock), and the wedge resection sample is obtained by the use of endoscopic staples (Fig. 47-2). When necessary, the atraumatic forceps and staple device are interchanged between portals to facilitate the approach to the tissue specimen. Because the tissue sample is usually too large to be withdrawn through the trocar–cannula system, it is withdrawn through the instrument portal with the cannula. The thoracic cavity and biopsy site are inspected for evidence of hemorrhage. Negative pressure of the thoracic cavity is reestablished by removing all the air from the chest, and the skin is closed routinely.

PNEUMOTHORAX AND HEMOTHORAX
Clinical Signs
Pneumothorax refers to the accumulation of air in the pleural cavity, which occurs as a result of pulmonary or chest wall injury. When a communication between the atmosphere and the pleural space is created, a pressure gradient between the negative pressure in the pleural space and the alveolar or atmospheric pressure develops. Air enters the pleural cavity until the pressure gradient is eliminated or the communication is sealed. Consequently, the lung collapses to its minimal volume and this compromises pulmonary function. Meanwhile, the increase in pleural pressure causes a shift of the mediastinum to the contralateral side, enlarges the ipsilateral hemithorax, and depresses the diaphragm. Pneumothorax in horses has been reported secondary to thoracic trauma, secondary to pleuropneumonia, and as a complication of upper airway surgery. Traumatic pneumothorax can be classified by its physiologic nature as open or closed, or as a tension pneumothorax. Injury to the chest wall (e.g., from penetrating objects, wounds, gunshots) that creates a communication between the pleural cavity and the external environment produces an open pneumothorax.

Figure 47-2. Thorascopically guided lung biopsy in a horse. The caudodorsal aspect of the lung lobe is grasped with Babcock forceps (A), and using endoscopic staples (B), the pulmonary wedge resection is performed (C).
closed pneumothorax results from leakage of air from the pulmonary parenchyma or an airway tear and commonly takes place after blunt trauma that is accompanied by fractured ribs that injure the lung parenchyma. Tension pneumothorax results when an air leakage, whether from the thoracic wall or lung parenchyma, acts like a one-way valve, allowing entry of air into the pleural cavity but not permitting its escape. Air continues to accumulate inside the pleural cavity during subsequent respiratory cycles, thus progressively increasing intrathoracic pressure to a point that it exceeds atmospheric pressure (positive pressure). Increasing intrathoracic pressure causes severe cardiovascular and pulmonary deterioration, and if not treated promptly and aggressively, this condition can be fatal.27 Severe pleuropneumonia is another cause of pneumothorax in horses. Slow leaks of air from necrotic pulmonary tissue or the formation of bronchopleural fistulas may be the source of pleural air in these horses.

The main physiologic consequences of pneumothorax are a decrease in the vital capacity of the lung and a decrease in the partial pressure of arterial O2 (Pao2).27 Patients with pneumothorax have a reduced Pao2 and an increased alveolar–arterial oxygen difference (A-a gradient). These physiologic changes appear to be caused by ventilation/perfusion mismatching (low V/Q ratio), intrapulmonary shunts, and alveolar hypoventilation.27,28 Unless the mediastinum is sealed by another underlying inflammatory condition (e.g., pleuropneumonia, hemothorax), pneumothorax is frequently bilateral because an incomplete mediastinum exists in the horse.29

Clinical signs associated with pneumothorax include restlessness, cyanosis, tachypnea, dyspnea, unilateral expansion of the thorax, and accentuated respiratory excursions. In the absence of lower airway disease, the most probable cause of pneumothorax is trauma, and further examination may reveal evidence of a penetrating wound. Acute clinical signs are usually observed in horses with acute onset of pneumothorax or tension pneumothorax, whereas a more insidious onset of clinical signs is typical in horses with pleuropneumonia.7 Decreased lung compliance and increased intrathoracic pressure increase the work of breathing.28 To minimize the work of breathing, respiratory frequency increases, and the tidal volume decreases, producing the characteristic shallow, rapid breathing pattern observed in horses with pneumothorax.5

Hemothorax can develop secondary to any trauma that causes laceration of the intercostal blood vessels, myocardium, pulmonary parenchyma, or thoracic wall musculature. A horse with massive hemorrhage from laceration of the heart or one of the great vessels usually does not survive. Horses with hemothorax commonly present with signs of hypovolemic shock, anemia, and pain. Signs of respiratory distress develop once a large accumulation of blood in the pleural cavity restricts full expansion of the lungs, or when hemothorax is combined with pneumothorax.

Management

The emergency management of patients affected by pneumothorax is aimed at providing adequate ventilation, oxygenation, and systemic perfusion. Immediate therapy includes establishing a patent airway, reestablishing adequate alveolar ventilation by removal of the free air, and preventing recurrence. Supplemental oxygen therapy must be initiated for the treatment of hypoxemia (Pao2 less than 80 mm Hg). Nasal insufflation of oxygenation at a flow rate of 15 L/min is recommended in adult horses to increase the inspired oxygen concentration.5 In addition, patients with evidence of shock, such as tachycardia, weak peripheral pulses, peripheral vasoconstriction, and prolonged capillary refill time, require aggressive fluid volume replacement therapy.

Treatment of uncomplicated closed pneumothorax can be as simple as restriction of exercise and close monitoring. An open penetrating wound should be sealed immediately with a sterile, airtight bandage to convert the condition to a closed pneumothorax. Once sealed, thoracocentesis and reestablishment of negative pleural pressure can proceed. A large-gauge needle, Iat cannula, or thoracostomy tube is inserted between the 12th and 15th intercostal spaces just below the epaxial muscles.6 Air should be removed slowly from the pleural cavity, using a 60-mL syringe and a three-way stopcock or a suction device. Air leaks that recur after two to three needle aspirations require tube thoracostomy for intermittent or continuous evacuation. Thoracostomy tubes can be attached to a Heimlich valve for one-way flow (see Chapter 18), or to a pressure-regulated suction system such as the commercially available Pleuro-Evac (Genzyme Biosurgery, Fall River, Mass). Resolution of pneumothorax results in dramatic improvement in hemodynamic parameters, although abnormalities in gas exchange persist for 60 to 90 minutes after recovery and are associated with a decrease in pulmonary compliance.26 After reflationation of the lung, some areas of V/Q mismatch and intrapulmonary shunts persist for several hours.

Unilateral pulmonary edema, also known as reexpansion pulmonary edema, can occur after rapid expansion of the lung following a period of collapse as the result of pneumothorax or pleural effusion.30 Pulmonary edema acutely develops after reflation and causes hypoxemia, decreased cardiac output, and transient hypotension, and may lead to death.31,32 The pathophysiology is poorly understood; it appears that multiple factors contribute to increased vascular permeability in the alveolar capillary bed. The inflammatory response occurring after reexpansion of the lung is a strong predisposing factor for the development of pulmonary edema. The increase in capillary permeability is believed to be secondary to (1) mechanical vascular injuries to the alveolar capillary membrane and (2) reperfusion injury as blood flow returns to the now fully expanded lung.11,12 Typically, the chance for development of reexpansion pulmonary edema is increased if the pneumothorax has been present for several days or when extremely negative pressure is used to evacuate the pleural cavity. A pressure of −20 mm Hg or less should be applied to the pleural cavity, and slow evacuation is recommended to minimize the chances of developing this complication.35

The rate of pleural air absorption can be accelerated by tracheal administration of 100% supplemental O2.36 When 100% O2 is administered, the partial pressure of nitrogen in the pulmonary vessels is decreased to near zero, whereas the partial pressure of oxygen, carbon dioxide, and water remain unchanged. The absence of nitrogen in the dissolved gases in the pulmonary vessels establishes a diffusion gradient for
nitrogen between the air in the pleural cavity and the gases in the pulmonary vessels. Once the nitrogen is absorbed, oxygen is 100% of the gas in the pleural cavity, which results in a gradient for uptake of oxygen. This gradient can increase the speed of absorption of free air to approximately 10 times the absorption achieved while breathing room air.37 This therapy has been proven to be clinically effective in humans, but more investigations are necessary in horses.

Treatment of hemothorax involves restoration of the blood volume by use of intravenous fluids, blood transfusion, and pleural drainage. Removing the free blood from the thorax and reexpansion of the lung improves ventilation. In horses with open thoracic wounds, free blood should be removed to avoid the risk of developing septic pleuritis and pleural adhesions. Treatment of the simple hemothorax that is a complication of lung biopsy, thoracoscopy, or blunt trauma may be conservative unless the horse displays signs of respiratory distress, but careful monitoring is mandatory.38 In these horses, absorption of blood occurs within days and pleural adhesions are unlikely.

Thoracocentesis is commonly used to reestablish adequate alveolar ventilation in patients with pneumothorax and pleural effusion. Evacuation of air or fluid from the chest improves ventilation/perfusion matching and reduces intrapulmonary shunting.39 The site for thoracocentesis should be based on auscultation, or ideally on radiography and/or ultrasonography. In the case of both hemothorax and pneumothorax, both fluid and air can be evacuated from the same site. A large area over the selected site, usually the seventh and eighth intercostal space, should be clipped and prepared for an aseptic intervention. Local anesthetic is infiltrated into the skin, subcutaneous tissue, intercostal musculature, and costal pleura. A large-gauge needle, teat cannula, Chamber's catheter, or chest tube can be used for the procedure. The site for thoracocentesis is selected cranial to the rib to avoid the intercostal vessels located caudal to the rib. A small stab incision is made through the skin, and the selected instrument is advanced through the intercostal muscles until resistance is decreased as the pleural space is penetrated. At this moment, fluid or air can be drained and the catheter can be redirected if neither fluid nor air is aspired. Thoracostomy tubes can be left in place after the catheter can be redirected if neither fluid nor air is aspirated. Thoracocentesis is used to equilibrate pleural pressure with atmospheric pressure and relieve the respiratory insufficiency.

An important goal in the management of thoracic trauma is pain relief. All horses with thoracic wounds can have severe pain that limits chest wall excursions, and this often results in ventilatory impairment. Appropriate analgesia allows patients to maintain effective ventilation and oxygenation and to preserve the cough mechanism necessary to eliminate pulmonary secretions. Pain can be reduced by use of systemic analgesics and intercostal perineural anesthesia. Analgesics must be used carefully because of the potential for respiratory depression. Intercostal nerve blocks are performed with long-acting local anesthetic agents such as 5% bupivacaine. The block is performed dorsal and one to two intercostal spaces cranial and caudal to the injury to provide optimal local analgesia. Deeper infusion of local anesthetics is necessary to desensitize nonmyelinated C fibers located within the parietal pleura, which are a source of pain when stimulated by the penetrating object, fractured ribs, or wounds.20

Once life-threatening conditions are controlled, thoracic wound care consists of exploration, débridement, and closure. These manipulations can be accomplished with the horse standing under adequate analgesia or recumbent under general anesthesia. Treatment with the horse standing is preferred to avoid potential respiratory and cardiovascular complications that may develop under general anesthesia. General anesthesia is indicated for extensive wounds, for wounds that may involve underlying structures (e.g., the diaphragm), or for fractious animals. The horse must be stabilized by treating shock and respiratory impairments before the induction of anesthesia and, if necessary, the

**THORACIC WOUNDS**

**Etiology**

Injury to the thorax in horses is uncommon but not rare, possibly because automobile accidents involving horses are infrequent. Most referral hospitals have one or two cases a year presented to them. Penetrating wounds to the thorax generally occur after an impact with sharp objects (e.g., trailers, gates, trees). Penetrating wounds are usually located in the lateral aspect of the thoracic wall or in the region of the thoracic inlet. The defect may look like a simple perforation requiring no specific treatment, or it may be extremely large. Open pneumothorax and subcutaneous emphysema are the most common clinical findings that develop subsequent to penetrating thoracic wounds.2 The prognosis for horses with penetrating thoracic wounds is favorable if no other abdominal or musculoskeletal injury is present.2 However, septic pleuritis can alter the prognosis in these horses.40,41 Although a low incidence of septic pleuritis has been reported following thoracic trauma, approximately 50% of horses that developed pleuritis die or are euthanized.41

Axillary wounds create interesting clinical signs for affected horses. The injury might not involve the thorax initially; however, marked subcutaneous emphysema may develop because the wounded tissue becomes a one-way valve for air as the horse moves. When extensive, this subcutaneous emphysema can migrate to the mediastinum (pneumomediastinum) and extend into the thorax, leading to life-threatening pneumothorax. Therefore, horses with axillary wounds should be kept in strict confinement and monitored closely for signs of respiratory distress.

**Management**

Initial management of horses with thoracic wounds includes (1) the immediate covering of the wound with a sterile dressing to prevent any further ingress of air to the thoracic cavity and (2) assessment of the patient for intrathoracic injuries. Pneumothorax and hemothorax are likely to require treatment. If the wound is properly sealed, a one-time thoracocentesis or needle aspirate can alleviate the pneumothorax and associated ventilatory consequences. Any residual air in the pleural cavity will be reabsorbed within a few days. In horses with tension pneumothorax, emergency thoracocentesis is necessary to equilibrate pleural pressure with atmospheric pressure and relieve the respiratory insufficiency.
surgery should be delayed for 2 to 3 days. The wound must be thoroughly explored for the presence of foreign material and bone fragments, which can become the source of septic pleuritis or of recurrent purulent discharge. Thoracoscopy can be utilized to remove foreign objects while allowing a thorough inspection of thoracic structures.42 The telescope is initially inserted into the thoracic cavity via a portal away from the wound, and a detailed thoracic exploration is performed. Meanwhile, pleural lavage with sterile saline solution can be performed. The wound can also be explored with the use of the telescope, but, to avoid further contamination of the pleural cavity, this is not recommended.

Immediate or delayed closure techniques may be used depending on the hemodynamic status of the patient, and the degree of contamination and tissue damage. The wound is irrigated with sterile saline solution and subjected to debridement. To facilitate assessment of damaged ribs, diaphragm, and lung lobes, the wound may need to be enlarged. Any foreign body is removed and ideally primary closure of the wound is attempted. However, large thoracic defects may require reconstruction with primary muscle flaps, diaphragmatic advancement flaps, and/or prosthetic mesh. Creation of muscle pedicles from the longissimus dorsi and external abdominal oblique muscles to close a thoracic wall defect in a horse has been described.43 If the wound defect cannot be closed, the wound is packed and sealed with moist, sterile laparotomy sponges to prevent the entry of air. A stent and thoracic bandage around the thorax holds the packing in place. Horses are also given broad-spectrum systemic antibiotics, nonsteroidal anti-inflammatory drugs, analgesic medications, and tetanus prophylaxis. The wound is allowed to heal by secondary closure with fresh bandage changes daily until the thoracic cavity seals.

**FRACTURED RIBS**

Rib fractures are common after thoracic trauma. Complications of rib fractures include underlying pulmonary contusion and thoracic wall pain. The most substantial physiologic impairment after rib fracture is a decrease in dynamic compliance, resulting in ventilatory impairment.44 In addition, underlying pulmonary contusion renders a portion of the pulmonary parenchyma unavailable for adequate ventilation and oxygenation, resulting in hypocarbia and hypoxemia.45

Most isolated fractures heal spontaneously and surgical fixation is not necessary. The main goal for management of rib fractures is pain relief. Analgesia can be provided by administration of nonsteroidal anti-inflammatory drugs and by use of local intercostal nerve blocks. In the case of penetrating wounds, bone fragments are removed and rib edges are smoothed with rongeurs to prevent trauma to the pulmonary parenchyma.46 The horse should be strictly confined and monitored for signs of respiratory distress.

**Rib Fractures in the Neonate**

A recent study revealed that approximately 21% of the foals up to 3 days of age have thoracic trauma, which can include rib fractures and costochondral dislocation.1 In most foals, no clinical problems develop and the outcome is favorable. However, thoracic trauma and fractured ribs can have harmful effects and are a substantial contributor to morbidity and mortality in affected neonates.47 Hemorrhage, pneumothorax, diaphragmatic hernia, and even sudden death can result after laceration of intrathoracic vessels, lung parenchyma, and cardiac tissue by displaced fracture ribs. Underlying pulmonary contusion can also result in pulmonary insufficiency and predispose the foal to the development of pneumonia. Thoracic trauma in neonates usually involves three or more ribs, frequently occurs in one hemithorax, and is consistently located in the cranioventral aspect of the thorax.48 The most common site for injury is the costochondral junction and the area immediately proximal to it. Dystocia and foaling in primiparous mares are two factors associated with thoracic trauma in foals.49 These clinical findings and the occurrence of this condition during the first week of life suggest that injury occurs during parturition. The cause is believed to be pressure on the thorax during passage of the foal through the pelvic canal, but the thoracic circumference or the foal’s weight does not appear to be a factor in the development of thoracic trauma.

Clinical signs that may create suspicion of fractured ribs in foals include asymmetry of the thoracic cavity, groaning or grunting with respiration, plaques of subcutaneous emphysema overlying the ribs or ventral thorax, and crepitation or pain on palpation of the affected ribs. In a field study, 90% of affected foals were detected by palpation with the foal standing, but the thoracic cage asymmetry was better appreciated with the foal in dorsal recumbency.1 Ultrasonography permits characterization of associated thoracic abnormalities. The presence of unilateral or bilateral pleural fluid, pulmonary contusion, or pericardial effusion, the number of fractured ribs, and the degree of fragment displacement are better evaluated with ultrasonography than with radiography.46 Because more than three ribs are usually involved, affected foals can present with flail chest. Flail chest occurs when multiple ribs are fractured in two places (dorsal and ventral), resulting in loss of stability in a segment of the thoracic wall, known as the flail segment. The flail segment can also develop when ribs fracture in a single dorsal plane and the flexible costochondral junction becomes the second movement plane.48 Respiratory efforts are hindered by the failure of the affected flail segment to expand and participate in the normal process of respiration. However, the underlying pulmonary contusion, not the mechanical disruption of the thoracic wall, causes the respiratory insufficiency.49

Management of foals with simple rib fractures consists of strict confinement for 1 to 4 weeks and supportive care with analgesics, anti-inflammatory drugs, antibiotics, and antiulcer medications. Foals with flail chest and concomitant pulmonary trauma are kept recumbent with the affected side down, and intranasal oxygenation is administered. Lateral recumbency with the affected lung down minimizes ventilatory impairment of the better-ventilated lung (on top).8 Foals are kept in recumbency and sedated as necessary until the respiratory difficulties improve. However, lateral recumbency may lead to intrathoracic damage if axial displacement of the fracture is present. In these cases, foals can be placed in sternal recumbency. Surgical intervention is usually not necessary, but it has been pursued in foals when there is a potential for intrathoracic injury, as can occur with axial displacement of fracture fragments. There are reports of
the use of both external coaptation and internal fixation of the affected ribs.\(^{46,50}\) External coaptation was achieved by placing stainless steel suture material around the ribs and fixing the wires to cast material molded to the rib cage.

Internal fixation seems to be a better option to successfully manage foals with complicated rib fractures, or when the risk of intrathoracic injury is high. A recent report evaluated the repair of rib fractures using internal fixation techniques in 14 foals.\(^{50}\) Surgical management was performed because the foals were considered at great risk for developing life-threatening injuries. A surgical procedure was performed on an average of two ribs (one to three ribs). After fracture reduction was achieved, a 2.7-mm reconstruction plate (Synthes, West Chester, Pa) was contoured to the rib and applied with 2.7-mm-diameter cortex screws engaging both cortices (Fig. 47-3). Four to six cortices of fixation on each fracture fragment were recommended. In addition, cerclage wire (18 to 22 gauge) was placed encircling the rib and plate at two sites above and two sites below the fracture. Application of the cerclage wire prevented implant failure from pullout of the cortex screws. Stall confinement was recommended from 4 to 6 weeks or until healing, which was evaluated with the use of ultrasonography. Of 14 foals treated using internal fixation, 12 were discharged from the hospital. Follow-up information on seven foals revealed that all were in good health and performing as expected, with the plates left in situ. Complications occurred in six foals and included implant failure, seroma formation, and subcutaneous hematoma.\(^{50}\) Broad-spectrum systemic antibiotics, nonsteroidal anti-inflammatory drugs, and analgesic medications are also recommended.

CHAPTER 48

Pleuropneumonia

Elizabeth A. Carr

Joel Lugo

Pleuropneumonia is a serious disease in the horse, and it has a significant economic impact on the equine industry. Treatment of horses with bacterial pleuropneumonia is frequently expensive, and it is time consuming. Resolution of the infection and response to therapy can be prolonged, even with early detection and aggressive treatment. Survival rates vary from 43% to 75% depending on the microbial pathogens involved, the rapidity of diagnosis and institution of appropriate treatment, and the development of secondary complications.13 Many survivors are unable to return to their previous level of performance.1

RISK FACTORS

Bacterial pleuropneumonia most commonly occurs in horses subjected to physiologic stress, including long-distance transport, high-speed exercise, general anesthesia, and recent viral infection.1,2,4,5 Horses subjected to long-distance transport have higher numbers of circulating neutrophils, an increased neutrophil-to-leukocyte ratio, elevated plasma cortisol levels, and decreased phagocytic function of peripheral blood neutrophils.6,7 In addition, the practice of shipping horses with their heads secured in an elevated position results in increased bacterial and pollutant contamination of the lower airway compared with individuals allowed to lower their heads during transport.8,9 Many horses refuse to drink appropriately during transport, and subsequent dehydration further compromises mucociliary clearance mechanisms.10 During extended travel, periodic rest stops allowing the horse to lower its head and drink are necessary to resolve this contamination problem and to facilitate the correction of dehydration. However, rest stops may be infrequent with commercial hauling operations; consequently, the shipped horse is at increased risk of infection of the lower airway.

High-intensity exercise results in transient decreased peripheral blood neutrophil function and oxidative burst activity of pulmonary alveolar macrophages.11,12 In the United States, Thoroughbred horses in race training are 4.3 times more likely to develop pleuropneumonia than nonracing Thoroughbreds, suggesting that career, not breed, is the risk factor.1 In contrast, in Great Britain, show jumpers have the highest risk of developing pleuropneumonia.13 The reason for this difference may be partly because most races are run on turf in the United Kingdom but on dirt in the United States. Additionally, European show jumpers frequently travel long distances for competitions, which may explain the increased risk in horses in this discipline.13

Endotracheal intubation, dorsal recumbency, and anesthetic-induced depression of the respiratory defense mechanisms may all increase the risk of lower airway contamination with general anesthesia. Respiratory viral infections result in damage to airway epithelium and breakdown of clearance.

Pleuropneumonia is a serious disease in the horse, and it has a significant economic impact on the equine industry. Treatment of horses with bacterial pleuropneumonia is frequently expensive, and it is time consuming. Resolution of the infection and response to therapy can be prolonged, even with early detection and aggressive treatment. Survival rates vary from 43% to 75% depending on the microbial pathogens involved, the rapidity of diagnosis and institution of appropriate treatment, and the development of secondary complications. Many survivors are unable to return to their previous level of performance.

RISK FACTORS

Bacterial pleuropneumonia most commonly occurs in horses subjected to physiologic stress, including long-distance transport, high-speed exercise, general anesthesia, and recent viral infection. Horses subjected to long-distance transport have higher numbers of circulating neutrophils, an increased neutrophil-to-leukocyte ratio, elevated plasma cortisol levels, and decreased phagocytic function of peripheral blood neutrophils. In addition, the practice of shipping horses with their heads secured in an elevated position results in increased bacterial and pollutant contamination of the lower airway compared with individuals allowed to lower their heads during transport. Many horses refuse to drink appropriately during transport, and subsequent dehydration further compromises mucociliary clearance mechanisms. During extended travel, periodic rest stops allowing the horse to lower its head and drink are necessary to resolve this contamination problem and to facilitate the correction of dehydration. However, rest stops may be infrequent with commercial hauling operations; consequently, the shipped horse is at increased risk of infection of the lower airway.

High-intensity exercise results in transient decreased peripheral blood neutrophil function and oxidative burst activity of pulmonary alveolar macrophages. In the United States, Thoroughbred horses in race training are 4.3 times more likely to develop pleuropneumonia than nonracing Thoroughbreds, suggesting that career, not breed, is the risk factor. In contrast, in Great Britain, show jumpers have the highest risk of developing pleuropneumonia. The reason for this difference may be partly because most races are run on turf in the United Kingdom but on dirt in the United States. Additionally, European show jumpers frequently travel long distances for competitions, which may explain the increased risk in horses in this discipline.

Endotracheal intubation, dorsal recumbency, and anesthetic-induced depression of the respiratory defense mechanisms may all increase the risk of lower airway contamination with general anesthesia. Respiratory viral infections result in damage to airway epithelium and breakdown of clearance mechanisms.
mechanisms, further increasing the risk of bacterial colonization of the lower airway. Penetrating thoracic injuries and pulmonary aspiration secondary to esophageal obstruction or upper airway dysfunction have also been associated with an increased risk of pleuropneumonia.

CLINICAL SIGNS
Clinical signs vary depending on the chronicity and severity of disease and on the volume of pleural effusion. In the peracute stage, fever, inappetence, lethargy, depression, and exercise intolerance are common. Pleurodynia (pleural pain) secondary to pleural inflammation may be manifested by anxiety, pawing, reluctance to move, abduction of the elbows, and grunting when the thorax is percussed. A soft cough, dyspnea, tachypnea, and tachycardia may or may not be present during the peracute phase. Lung sounds vary depending on the severity of pulmonary and pleural changes, and a rebreathing examination is recommended to increase the depth of respiration and accentuate audible lung sounds. Although lung sounds may be relatively normal during the peracute stages, the patient often becomes distressed by the rebreathing examination (because of increased pleural pain) and may begin to cough violently.

With progression of the disease and accumulation of pleural effusion (acute to chronic stages of the disease), auscultation reveals ventral dullness with pleural friction rubs and adventitial sounds (crackles and wheezes) in the dorsal lung fields. Areas of dullness can also correlate with pulmonary or pleural abscessation. Cardiac sounds frequently radiate over a larger than normal area as a result of the pleural effusion and improved sound conduction. Nasal discharge can vary between absent and copious, and can range in consistency from serous to purulent. A chronic, brown, bloody nasal discharge may be indicative of pulmonary hemorrhage and infarction. A foul, fetid odor to the breath is frequently associated with anaerobic infections.

Accumulation of pleural effusion results in an increased respiratory effort with a slow prolonged pattern of inspiration and expiration. This pattern is the result of pleural fluid accumulation and its effects on lung volume and expansion of the chest wall. Edema can frequently be palpated between the pectoral muscles and along the ventral midline, and it is a nonspecific finding with pleural effusion. Dramatic weight loss over a relatively short time results from the catabolic nature of the disease coupled with a decreased (or absent) appetite.

DIAGNOSIS
The diagnosis of bacterial pleuropneumonia is based on clinical findings (fever, pleural pain, abnormal lung sounds), complete blood count abnormalities, ultrasonographic and radiographic findings, coupled with positive bacterial culture of a tracheal wash and pleural fluid sample. Thoracic percussion can be used to detect and outline the extent of pleural effusion or pulmonary consolidation. The line of demarcation between resonant percussive sounds and dull sounds is usually the dorsal margin of pleural fluid accumulation. Fluid results in a horizontal line of percussion abnormality, whereas pulmonary consolidation without effusion generally results in a more irregular outline of dullness.

Thoracic ultrasound has largely replaced the need for percussion and is a simple and accurate way to assess the volume and type of effusion, if one is present (Fig. 48-1). Pleurocentesis is indicated if fluid is detected, and ultrasonography is used to determine the ideal site for the cenhesis. An ultrasonographic examination of the thorax in the peracute stage may reveal pleural irregularities (Fig. 48-2) without significant effusion or evidence of pulmonary consolidation. As the disease process progresses, pleural effusion generally increases and pulmonary consolidation becomes increasingly evident (Fig. 48-3). Because of the large reflection of ultrasound waves at an air–tissue interface, ultrasound is less useful in determining deep lung abscessation or consolidation if the superficial lung is aerated. In this situation, thoracic radiography is a more effective tool for evaluating deeper pulmonary parenchymal
lesions (Fig. 48-4). Drainage of pleural effusion prior to thoracic radiography facilitates accurate evaluation since pleural fluid obscures the lung parenchyma, making it difficult to evaluate the extent or presence of consolidation or abscessation. Radiographs are useful, both to determine the extent of pulmonary consolidation and to evaluate progression over time; however, radiographic resolution of disease lags behind clinical resolution and, in the authors’ experience, radiographic reevaluation is more useful in evaluating long-term progression than short-term changes.

Complete blood count and serum chemistry abnormalities are relatively nonspecific and reflect the chronicity and severity of the inflammatory processes. Hyperfibrinogenemia and a neutropenia with a toxic left shift are frequently seen in the acute stage of pleuropneumonia. Other common abnormalities may include hyperbilirubinemia (or anorexia) and azotemia (prerenal or renal). Neutrophilia is more commonly seen in the chronic stage of pleuropneumonia; an elevated serum globulin and anemia of chronic disease are also common. Although the abnormalities seen are nonspecific, they are useful in evaluating the response to treatment. A gradual decrease in serum fibrinogen and globulin levels, an improvement in the anemia, and a decrease in unconjugated bilirubin concentration (improved appetite) would be considered positive responses to therapy.

Both aerobic and anaerobic microbial culture of tracheal wash and pleural fluid samples should be performed prior to instituting antimicrobial therapy. Alternatively, antimicrobials can be withdrawn for 24 hours prior to sample collection. Tracheal wash samples can be collected percutaneously using a nested trocar or via endoscopic techniques. Both methods are effective in experienced hands. Complications of the percutaneous method include localized cellulitis and chondritis; therefore, the site should be monitored carefully for 48 hours after sample collection. If multiple samples cannot be obtained from the chest or if financial constraints exist, the tracheal wash is the preferred sampling technique, yielding positive results with a greater frequency than pleural fluid samples. However, in some cases, only the pleural fluid yields bacterial growth. Consequently, when possible, it is best to submit both sample types for culture. The most common organisms isolated include *Streptococcus, Escherichia coli, Actinobacillus, Klebsiella, Pseudomonas,* and *Staphylococcus.* Common anaerobes include *Bacteroides* and *Clostridium.* Anaerobic bacteria were isolated in 25% to 68% of cases.

In addition to culture, cytologic analysis of a sample of transtracheal aspirate can be useful to assess the type of infectious process present, and to aid in determining the appropriate treatment protocol while awaiting culture results. For example, the presence of large, gram-positive cocco-bacilli from the transtracheal wash of a weanling foal may be indicative of a *Rhodococcus equi* infection. Alternatively, the presence of fungal elements, particularly if a horse has been on long-term antimicrobial treatment, may indicate infection with fungal agents. In addition to culture, cytologic analysis of a sample of transtracheal aspirate can be useful to assess the type of infectious process present, and to aid in determining the appropriate treatment protocol while awaiting culture results. For example, the presence of large, gram-positive cocco-bacilli from the transtracheal wash of a weanling foal may be indicative of a *Rhodococcus equi* infection. Alternatively, the presence of fungal elements, particularly if a horse has been on long-term antimicrobial treatment, may indicate infection with fungal agents.

Pleural fluid cytology alone is of limited value in determining sepsis and should be coupled with the determination of pleural fluid glucose, pH, and lactate. In general, septic effusions are expected to have a low pH and high lactate and low glucose levels when compared with plasma. The finding of sepsis is a clear indication for drainage. Serial pleural fluid protein measurements and cell counts are useful to determine progress and resolution of infection. A trend toward normalization of pleural fluid values is expected with appropriate treatment and control of the infectious agents.

**MEDICAL MANAGEMENT**

The cornerstone of medical treatment of bacterial pleuropneumonia is **early institution of appropriate antimicrobial therapy.** Treatment should be initiated with a broad-spectrum antimicrobial combination targeted against the most common bacterial pathogens isolated from equine pleuropneumonia cases, until specific culture results are available. A combination of penicillin (or cephalosporin) and an aminoglycoside is a typical selection. Although many
anaerobes found in equine pleuropneumonia are sensitive to penicillins, the addition of metronidazole is recommended if there is a lack of response to initial treatment or a resistant anaerobe (such as *Bacteroides fragilis*) is cultured. Depending on the chronicity of the disease, the type of sample cultured, and prior treatment, a culture may not always identify the pathogens involved; consequently, it is critical to monitor the patient’s response to treatment. Repeat cultures or alternative antimicrobial therapy is indicated if the response to therapy is inadequate. In the authors’ experience, a poor response to treatment typically occurs for one of three reasons: inappropriate antimicrobial treatment, inadequate pleural drainage, or the presence of abscession or necrotic lung tissue. Therefore, daily assessment including by ultrasonography is critically important in the successful treatment of pleuropneumonia. When subcutaneous air prevents an accurate ultrasonographic evaluation, thorcoscopy is a useful and relatively safe tool to assess the development of pleural abscesses or necrotic lung tissue.

The second important part of medical management is drainage of the pleural effusion. In mild cases, with minimal effusion, antimicrobial therapy alone may be effective in resolution of the infection and the effusion. The need for drainage should be determined on an individual basis. Indications include large volumes of effusion with or without evidence of respiratory distress, purulent or septic effusions, the presence of gas echoes consistent with an anaerobic infection, and pleural abscession or loculation. In the acute stages of pleuropneumonia, drainage of one hemithorax frequently results in bilateral resolution of the effusion. Over time, the accumulation of fibrin and debris results in closure of the mediastinal fenestrations, requiring bilateral thoracocentesis to remove bilateral effusion.

Drainage can be facilitated by ultrasound-guided placement of small cannulas or catheters that are temporarily placed into the pleural space and removed after completion of drainage, or via placement of a semipermanent indwelling tube. Indwelling tubes have the advantage of allowing frequently repeated drainage; however, in the authors’ experience, over time these tubes become obstructed with fibrin or debris, necessitating removal and replacement. Attachment of a one-way valve allows continuous drainage, but this can be risky if the horse rolls or otherwise breaks the valve. Alternatively, the drain can be sealed and opened multiple times during the day to allow more control of the drainage. Localized cellulitis is a frequent complication of indwelling cannulas. Although this is generally not a life-threatening complication, it results in increased thoracic pain and is frequently associated with a poorer appetite and general demeanor. Depending on the severity of the underlying pulmonary parenchymal disease and the type of bacteria involved, drainage can become increasingly more difficult as fibrin is produced, and abscessation and loculation develop. Prior to the development of thorascopic techniques, one of us (EAC) successfully treated cases with multiple, mature, pleural abscesses by repeated ultrasound-guided pleurocenteses and drainage. Although this was time consuming, it can be a useful technique to manage cases with multiple abscesses or loculations.

The judicious use of anti-inflammatory and analgesic drugs is recommended to control pleural pain and fever, minimize malaise, and improve attitude and appetite. Nonsteroidal anti-inflammatories (NSAIDs) are potent analgesics and block production of inflammatory mediators that produce many of the systemic signs seen with pleuropneumonia. The value of NSAIDs in the treatment of pleuropneumonia needs to be weighed against the risks (nephrotoxicity and gastrointestinal ulceration), particularly in patients that are not eating or drinking adequately. The short-term use of small intramuscular doses or continuous-rate infusions (CRI) of the α2 agonist detomidine, a potent analgesic, has been effective in controlling severe, non-responsive pleural pain in the experience of one of us (EAC).22 Alpha-2 agonists should be avoided in febrile or hypovolemic patients until these conditions are corrected. Butorphanol, a potent opiate analgesic, can be administered intramuscularly or via CRI as well, and it may have the added benefit of suppression of the cough response.23 Lidocaine infusions have also been reported to have an analgesic effect and may be an additional choice for pain control.24 The use of combination therapies offers several advantages over single drug treatment protocols, including more effective pain control and the ability to minimize potential toxic side effects.

**SUPPORTIVE CARE**

Intravenous fluid therapy may be necessary in the initial treatment of the hypovolemic or dehydrated patient, but it is seldom required for chronic cases of pleuropneumonia. In addition to fluid therapy, nutritional support should be addressed. Many of these patients have a decreased (or absent) appetite, which, coupled with the catabolic nature of the disease, results in significant, often dramatic, weight loss if not addressed quickly. Feeding of palatable feeds, access to grass, and gradually increasing concentrates in the diet are important methods to increase caloric intake. The addition of corn oil or rice bran to the diet may also be of benefit. In some individuals, enteral supplementation via nasogastric intubation or parenteral nutrition may be required to adequately supply the patient’s metabolic needs (see Chapter 6). Continued anorexia may be indicative of inadequate pain control, uncontrolled infection, or severe underlying lung pathology (pulmonary necrotic debris, abscessation, or neoplasia). Patients that continue to be anorexic despite aggressive therapy have a poor long-term prognosis.

**SURGICAL TREATMENT**

Surgical intervention is typically utilized to assist in the medical treatment of equine pleuropneumonia. Long-term antimicrobial therapy is rarely effective in penetrating and resolving large abscesses or loculations when substantial fibrosis or septic fluid is present.25 Open and closed thoracotomy, with or without rib resection, has been successfully used for drainage of thoracic abscesses and resection of adhesions.26-28 Surgical manipulations can be used to reduce excessive fibrin, which can result in loculations and adhesions, drain pulmonary or extrapulmonary abscesses, resect necrotic lung tissue, or perform pericardectomy in cases of septic pericarditis.26,30-32 Vachon and Fischer reported the use of thoracoscopy as a useful therapeutic tool in 16 cases of pleuropneumonia.32
Thoracoscopy facilitated the placement of thoracic drains in abscesses and loculated pleural effusion, and the transection of pleural adhesions to disrupt loculations, and it allowed direct evaluation of the lungs and pleural cavity (Fig. 48-5). Thoracoscopy provides a superior exploration of the pleural cavity compared with incisional thoracotomy. Furthermore, the minimally invasive nature of thoracoscopy results in less morbidity and aftercare. This procedure can be performed in the standing, sedated horse with local anesthesia. (For surgical approaches to thoracoscopy, see Chapter 47.)

After establishing adequate pleural drainage, pleural lavage can be performed with isotonic balanced fluid solutions through the cannula system. Adhesions are more readily disrupted the first week after formation when the tissue is fibrinous rather than fibrous. Transection of mature, fibrous adhesions can be difficult and tedious, and it can cause profound hemorrhage. Therefore, conservative transection of mature adhesions is recommended. Careful insertion of instruments or portals into the thorax is mandatory in horses with severe pleuropneumonia and with extensive pleural adhesions or anaerobic infections. Adhesions between the lungs and the thoracic wall may not allow complete collapse of the lung, making the manipulation of the instruments more difficult and limiting the view of the pleural cavity. This can increase the risk of injury to vital organs (e.g., lungs, diaphragm). Before introducing the trocar–cannula system in horses with possible adhesions, digital palpation of the lungs and pleura through the endoscope portal is recommended to avoid iatrogenic injury to these structures. In addition, the use of CO₂ insufflation (at less than 5 mm Hg) can facilitate and maintain collapse of the lung, improving surgical exposure.

Open drainage via thoracotomy should be considered for a chronic pleural effusion that has responded poorly to medical therapy, for localized or unilateral disease processes, for walled-off abscesses, or when tube drainage is inadequate. Before performing open thoracic drainage, a horse’s tolerance for pneumothorax must be assessed. This can be done with thoracoscopy or by inserting a large chest tube into the targeted cavity and leaving it open prior to thoracotomy. If no respiratory distress is observed, the diseased pleural hemithorax is likely to be isolated from the rest of the thoracic cavity and is amenable to open drainage.

Because these horses have compromised pulmonary function and are poor candidates for general anesthesia, the procedure is typically performed with the horse standing. However, general anesthesia with the horse in lateral recumbency is recommended to drain abscesses in the cranial mediastinum or when an abscess is not isolated from the rest of the pleural cavity. Positive-pressure ventilation with a mechanical ventilator is mandatory. The use of isoflurane or sevoflurane is also recommended for gas anesthesia, because these drugs do not depress the equine myocardium as profoundly as halothane. Therefore, the combination of assisted ventilation, oxygen, and isoflurane or sevoflurane should be used to support horses undergoing a thoracotomy procedure when general anesthesia is required.

The preferred surgical approach to drain intrathoracic abscesses is determined by careful localization of the abscess by radiography and ultrasonography. For the standing approach, local anesthesia is infiltrated into the skin, subcutaneous tissue, intercostal musculature, and costal pleura at the proposed incision site, and a local nerve block of the intercostals nerves is performed two intercostal spaces cranial and caudal to the site (see Chapter 47 for details). A 15- to 25-cm incision is made through the skin, intercostal musculature, and pleura over the selected intercostal space into the thorax. Manual exploration and débridement of the purulent material is followed by lavage with isotonic balanced saline solution. The incision is left open and the diseased cavity is irrigated twice daily until the surgical wound heals by second intention.

If thoracotomy with rib resection is elected, a 30-cm incision is made over the selected rib, through the skin to rib periosteum. In the cranial aspect of the thoracic wall, the cutaneous trunci muscle is incised at a right angle to its fibers. The latissimus dorsi and serratus muscles are then incised separately. The external thoracic vein is identified near the dorsal edge of the pectoral musculature, isolated, and retracted. Careful dissection of thoracic wall musculature avoids damage to the intercostal vessels and nerves, which are located at the caudal aspect of each rib. To expose the entire length of the rib, the fascia from the attachment of the external intercostal muscle is bluntly dissected. The periosteum is incised along the superficial surface of the rib for a distance of 25 cm and reflected circumferentially with

**Figure 48-5.** Thoracoscopic view of the left pleural cavity in a horse with pleuropneumonia. **A,** The collapsed lung (L) is adhered to the parietal pleura by fibrinous adhesions (black arrow). **B,** With the use of endoscopic instruments, the lung is separated from the adhered parietal pleura. **C,** After adequate drainage was established, a large chest tube (arrow) was introduced into the thorax and the pleural cavity was lavaged with isotonic saline.
a periosteal elevator (Fig. 48-6). The periosteum is separated from the rib, and an obstetric wire is passed around the most proximal aspect of the rib and transected. The rib is then disarticulated at the costochondral junction and removed. A small stab incision should be made through the periosteum and pleura, and the opening is enlarged with scissors. A Finocchieto rib retractor can be used to separate the ribs for better surgical exposure, but this can cause discomfort in the standing horse. Thoracic exploration and débridement is then performed. Fluid and necrotic tissue are manually removed, taking care not to disrupt any mature adhesions. If a localized abscess is encountered, a Foley catheter can be introduced from a separate stab incision through the thoracic wall into the abscess. The abscess can then be drained and lavaged, and the catheter can be removed or left in situ and secured to the chest wall for future irrigation. The thoracic incision is usually left open to heal by second intention.

If closure of the thoracotomy is performed, three layers of sutures are recommended. A rib contraction device (Bailey-Gibbon rib contractor, Standard model, Miltex, Inc, York, Pa) may facilitate the apposition of the thoracic wall. First, the periosteum is carefully apposed with size 0 or 1 absorbable suture material with a simple-interrupted pattern. The final suture in the first layer of the thoracic wall closure should be tightened while the lungs are fully inflated to reestablish the normal negative pressure of the pleural cavity. The intercostal musculature is subsequently closed in routine fashion with size 1 or 2 absorbable sutures. Finally, routine apposition of the skin edges with nonabsorbable suture material is recommended. Thoracic tubes are placed as necessary to alleviate pneumothorax or to drain pleural fluid.

Complications after thoracotomy include cardiac arrhythmias, thoracic wall abscesses, chronic draining tracts, and severe bilateral pneumothorax. In contrast to thoracotomy, only mild discomfort during manipulation of instruments was reported during thoracoscopy in horses affected by pleuropneumonia. However, thoracoscopy is not without risk; complications including injury to vital organs such as the lung and diaphragm have been reported. In conclusion, surgical treatment does not replace medical management of equine pleuropneumonia but can, in selected cases, improve the prognosis of these horses.

PROGNOSIS

In retrospective reports, the survival rate for horses with bacterial pleuropneumonia varied from 43% to 75%. The presence of anaerobic bacteria has been associated with a poorer survival rate in some studies but not others. Delay between the onset of clinical signs and the diagnosis and start of treatment is also associated with a poorer outcome. The majority of horses that do not survive bacterial pleuropneumonia are euthanized for reasons including poor response to treatment, development of complications, expense involved in treatment, or a poor prognosis for return to performance. In a study of racehorses that survived pleuropneumonia, 61% returned to racing, with 56% of those winning at least one race. However, racing class was not examined in this report. Complications associated with pleuropneumonia include bronchopleural fistulas, spontaneous pneumothorax, cranial thoracic abscessation, jugular vein thrombosis, pulmonary infarction, laminitis, and, rarely, pericarditis and peritonitis.

A positive response to treatment is indicated by resolution of fever, return of appetite, and gradual reduction in the volume of effusion. Negative responses to treatment include recurrent fevers, continued inappetence and weight loss, continued effusion (particularly with progression of the effusion to an exudate), and development of the complications mentioned previously. These findings, coupled...
with a continued elevation in serum fibrinogen and globulins and an abnormal white blood cell count, should stimulate careful reevaluation of the individual. Even with appropriate and early treatment, the response is often slow, with treatment durations ranging from 3 weeks to several months. After resolution of the underlying infection at least 3 to 6 months of recovery time should be allowed prior to return to training and performance.

DEVELOPMENT AND ORGANIZATION OF THE NERVOUS SYSTEM

The nomenclature relating to embryologic, medical, and common description of the parts of the brain is inconsistently applied and can be confusing. Table 49-1 shows the principal naming systems used for the parts of the brain, Table 49-2 gives numeric and medical names for the cranial nerves, and Figure 49-1 depicts the locations of the cranial nerves on the ventral aspect of the brain.

The nervous system derives from a specialized strip of ectoderm, the neural plate, which runs along the dorsal midline of the developing embryo. Ventral to the neural crest is the primordial vertebral organ, the notochord, which develops in concert with the central nervous system (CNS). The sides of the neural crest fold upward and medially to meet in the midline and form the neural tube.

Beginning at the brain–spinal cord junction, the neural tube closes progressively both rostrally and caudally to encircle the developing brain and spinal cord. The rostral part of the neural tube buds large vesicles laterally on either side, which develop caudally and ventrally to form the hemispheres of the cerebrum (telencephalon), leaving the rest of the rostral tube to form the thalamus and hypothalamus (diencephalon) (see Table 49-1). The lumen of the neural tube (the neural canal) forms the interconnected ventricular system of the diencephalon (third ventricle) and cerebrum (lateral ventricles). Together, these structures become the forebrain (prosencephalon). Cranial nerves I and II arise from the forebrain (see Table 49-2). Successively more caudal dilations of the neural tube develop into the midbrain (mesencephalon) and hindbrain (rhombencephalon). The brain structures directly derived from the neural tube proper (namely, the diencephalon, midbrain, and hindbrain) make up the brain stem. As it develops, the neuropil, the dense feltwork of interwoven cytoplasmic processes of dendrites, neurons, and glial cells of the midbrain, encroaches on the neural canal until it is a narrow tube, the mesencephalic aqueduct. The rostral part of the hindbrain (metencephalon) develops into the pons and cerebellum, whereas the caudal part, which is contiguous with the spinal cord, forms the medulla oblongata (myelencephalon). Within the pons and medulla, the neural canal forms the fourth ventricle, connecting the mesencephalic aqueduct rostrally with the spinal (central) canal caudally. Cranial nerves III and IV (midbrain), V (pons), and VI to XII (medulla) develop in the ventrolateral brain stem. Within the neural tube of the developing spinal cord, primitive neurons become organized into mantle and marginal layers that become white and gray matter, respectively. Ventral mantle neurons grow through the surrounding marginal layer and course outside the neural tube to form ventral spinal nerve roots. Dorsal ganglia and roots form from the growth of neural crest cells centrally into the neural tube and distally to sensory structures. The developing gray matter becomes divided morphologically and functionally into dorsal, intermediate, and ventral columns. Ventral and dorsal roots and gray matter divide spinal cord white matter into three regions called funiculi. These are dorsal, lateral, and ventral on each side of the spinal cord (Fig. 49-2).

*Some authors exclude the cerebellum from definitions of the brain stem.
The Cranium

The cranium is made up of the occipital, sphenoid, ethmoid, interparietal, parietal, frontal, and temporal bones. These bones enclose a cranial cavity with a volume of approximately 650 mL in an adult horse. The roof of the cranium features large rostral and caudal concavities, which accommodate the hemispheres of the cerebrum and cerebellum, respectively (Fig. 49-3). The internal occipital protuberance separates these cavities dorsally and provides attachment for the tentorium cerebelli, the tent-shaped extension of the dura mater that forms a partition between the cerebrum and cerebellum. The occipital and petrous temporal bones encase the cerebellum dorsally and laterally. The cerebrum is covered dorsally largely by the parietal bones, with smaller contributions from the interparietal bone caudally and the frontal bones rostrally. The rostral or nasal wall of the cranial cavity is formed by the cribriform plate of the ethmoid, which separates the cranium from the

nasal cavity. It is perforated by numerous foramina through which olfactory nerve bundles pass. On the dorsal midline is the internal parietal crest, which furnishes attachment to the falx cerebri, the sickle-shaped fold of dura that separates the cerebral hemispheres. The forehead may be injured by impact to the frontal/parietal area of the skull. As a consequence of swelling, cerebral lobes may herniate under the falx or tentorium and compress other parts of the brain.

The floor of the cranial cavity is organized into three fossae. The rostral fossa supports the frontal and olfactory parts of the cerebrum. It is formed chiefly by the sphenoid bone. Caudally in this fossa is a bony shelf that covers the entrance to the optic canals and supports the optic chiasm. The optic nerves are firmly attached within the optic canals and may be injured within the canals by the to-and-fro motion of the brain after skull impact. From this point and may be injured within the canals by the to-and-fro motion of the brain after skull impact. From this point.

The middle fossa is the internal parietal crest, which furnishes attachment to the falx cerebri, the sickle-shaped fold of dura that separates the cerebral hemispheres. The forehead may be injured by impact to the frontal/parietal area of the skull. As a consequence of swelling, cerebral lobes may herniate under the falx or tentorium and compress other parts of the brain.

The vertebral column extends from the skull to the end of the tail. There are five regions: cervical, thoracic, lumbar, sacral, and coccygeal (caudal). The typical formula for the horse is C 7 T 14 L 5 S 5 Cy 15 - 21. Although regions of the spine vary as to details, the vertebral structure conforms to a common plan. Each vertebra comprises a body, an arch, and various processes. The body is a cylindrical mass oriented along the median plane and connected to other vertebrae by fibrocartilaginous discs. Together with the dorsal surface of the body, the arch completes the vertebral foramen, or ring. The arch consists of two lateral pedicles and a dorsal lamina. The intervertebral foramina, formed by the spaces between the arches of adjacent vertebrae, provide passage for spinal nerves and vessels. Successive vertebral rings are strung together by dorsal and ventral longitudinal ligaments to form the vertebral canal, a protective cylinder for the spinal cord, nerve roots, and cauda equina. The arch gives rise to articular processes at each end, a dorsal spinous process, and costal facets. There are at least five centers of ossification in each vertebra: one body, two arches, and epiphyseal plates at either end of the body.

The spine can be modeled biomechanically as three “columns.” The ventral column is composed of the ventral longitudinal ligament and the ventral half of the vertebral bodies and discs. The middle column is formed by the dorsal longitudinal ligament and the dorsal half of the bodies and discs, and the dorsal column consists of the arches, intervertebral joints, and associated ligaments. The degree of instability after spinal injury increases as more columns are impacted, and the prognosis for recovery decreases correspondingly.

In its neutral position, the spine presents a series of curves in the median plane. The cranial part of the cervical spine is concave ventrally, the cervicothoracic junction is markedly concave dorsally, the thoracolumbar spine exhibits gentle ventral concavity, and the lumbosacral junction has more marked ventral concavity. The vertebral canal varies in

The vertebral column is composed of the ventral longitudinal ligament and the ventral half of the vertebral bodies and discs. The middle column is formed by the dorsal longitudinal ligament and the dorsal half of the bodies and discs, and the dorsal column consists of the arches, intervertebral joints, and associated ligaments. The degree of instability after spinal injury increases as more columns are impacted, and the prognosis for recovery decreases correspondingly.
diameter as it progresses along the spine: within the atlas it is wide so as to house the dens and spinal cord, and there are cervicothoracic and lumbosacral dilations to accommodate the corresponding intumescences of the spinal cord. The sagittal diameters of the cervical vertebral foramina in horses of various sizes have been determined radiographically. Mean sagittal diameters for horses heavier than 350 kg varied from 21.3 mm for C4 to 27.4 mm for C7.

The cervical vertebrae are relatively large and long. The arch is thick and strong and forms large articular processes. The cranial articular processes are directed dorsomedially; the posterior, ventrolaterally. Disordered vertebral development, possibly related to osteochondrosis, commonly causes malformation and arthropathy of the cervical vertebrae in young adult horses (see Chapter 51). These changes may cause cervical stenotic myelopathy with ataxia of the limbs and trunk. Horses with these clinical signs are commonly referred to as wobblers.

The first two cervical vertebrae are modified to accommodate the movements and weight of the head. The atlas is composed of dorsal and ventral arches, lateral masses, and wings. The ventral arch has on its upper surface the fovea dentis, on which the dens rests. The dens projects forward from the body of the axis and is attached by strong transverse, alar, and apical ligaments to the atlas and occiput. The upper cervical area of performance and racing horses is prone to severe hyperflexion, hyperextension, and/or axial compressive forces caused by collisions at speed. Such stresses may fracture any of the bony components of the upper (cranial) part of the neck or may separate the dens from the atlas.

Thoracic vertebrae are relatively constrained in their ranges of intervertebral movement. Added stability is provided to this region by the bracing action of the ribs and sternum. Perhaps because of the comparatively unconstrained movement of the cranial lumbar spine, fractures or dislocations of the vertebrae around the thoracolumbar joint occur quite commonly.

The sacrum is formed by the fusion of five sacral vertebrae. It is wedged between and attached to the ilia. Branches of the first four sacral nerves course through the dorsal and ventral sacral foramina. Fusion proceeds from the front of the sacrum caudally and may not be complete even in adult horses. The sacrum houses the roots of the cauda equina and a small terminal part of the spinal cord that supplies the tail. These nerve roots are vulnerable to damage as a result of sacral fractures. Such injury may manifest as cauda equina syndrome (S2 to S5 roots) or as gait abnormalities in the pelvic limbs (S1 to S2).

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) envelops, bathes, and protects the CNS. It is produced at a high rate by the choroid plexuses of the lateral, third, and fourth ventricles, and more generally by the meninges and ependyma. CSF passes from sites of production in the ventricles, out through the lateral apertures of the fourth ventricles, and it subsequently flows forward over the cerebrum and caudally over the spinal cord (Fig. 49-4). The rate of production is independent of CSF pressure. Absorption takes place in convoluted arachnoid structures, which project, mushroom-like, into cerebral veins or venous sinuses. Flow at these arachnoid villi is pressure dependent and unidirectional from CSF to blood.

The CSF plays an extremely important role in CNS homeostasis. Changes in CSF composition, as occur in subarachnoid hemorrhage or bacterial meningitis, cause clinical changes out of proportion to the minor structural changes found in the underlying neuropil.

Cerebrospinal fluid is a modified transudate with lower potassium and calcium, and higher chloride, sodium, and magnesium concentrations than are found in plasma. Protein concentrations (60 mg/dL or greater) and cell counts (6 cells/µL or greater) are lower than in most other body cavities. In disease, changes in CSF composition are a useful diagnostic tool. CSF collection and analysis and myelography are described in Chapter 50.

The CNS is physically separated from circulating blood by an extensive blood–brain barrier and a relatively minor blood–CSF barrier. The blood–brain barrier is formed by
endothelial cells, support cells (such as astrocytes of the neuroglia and pericytes of the vascular system), and basal lamina. Endothelial cells of CNS capillaries are cemented together by continuous tight junctions. Foot processes of astrocytes (end feet) and long cytoplasmic processes of pericytes are closely adhered to the abluminal surfaces of CNS endothelial cells. These cells affect and support the barrier function of the endothelium. The basal lamina surrounds the endothelial cells and pericytes. A biochemical barrier against potentially injurious endogenous substances is provided by various endothelial enzymes including monoamine oxidases (e.g., epinephrine degradation) and aminopeptidases (e.g., enkephalins). Carrier and transport systems control traffic of some molecules across the blood–brain barrier. There is a Na/K-ATPase pump to regulate Na+ and K+, glucose transporters (including GLUT-1), amino acid transporters, and transcellular endocytosis systems for receptor-mediated transfer of insulin, immunoglobulin G, and transferrin into the CNS. Generally, diffusion of molecules across the blood–brain barrier depends on physico-chemical properties such as lipid solubility, polarity, and molecular weight. There is a close association between lipid solubility of compounds and their ability to cross the blood–brain barrier. The free, non-protein-bound, nonionized form of most drugs can passively diffuse into the CNS.

In healthy animals, the blood–CNS barrier limits the passage of immunoglobulins, complement, and potentially injurious unconjugated bilirubin. Penicillin and aminoglycosides are excluded from the normal CNS; however, the blood–brain barrier reportedly allows passage of therapeutic amounts of sulfonamide-trimethoprim, chloramphenicol, enrofloxacin, and ceftriaxone into the CNS of horses.

PHYSIOLOGY OF NEUROTRANSMISSION
The transmission and processing of information in the nervous system depends on the presence and distribution of different ion channels in neurons, the localization of synaptic circuits, and the synaptic effects of neurotransmitters.14

The nervous system functions through propagation of electrical signals via changes in cell membrane potential. The resting membrane potential is determined by flow of K+ through channels open at rest and by the activity of the Na/K-ATPase pump. In response to stimuli, neurons generate local potentials that can summate. When these potentials reach the threshold for opening voltage-gated Na+ channels, an action potential is triggered. The opening of Na+ or Ca2+ channels produces neuronal depolarization, whereas opening of K+ and Cl− channels decreases neuronal excitability.

Neurochemical pathways in the CNS can be divided into two main groups: relay systems and diffuse projection systems.2 Relay systems include the long sensory and motor pathways that connect neurons of peripheral nerves to centers in the brain. Spinothalamic, visual, vestibulospinal, and reticulospinal pathways are examples of relay systems. Diffuse projection systems modulate brain function by distributing signals from individual nuclei to multiple other (usually higher) areas of the brain. They consist of cholinergic and monoaminergic neurons in nuclei of the brain stem and subcortical areas.

The excitatory neurotransmitter for relay systems is t-glutamate and, in some areas, aspartate. Local inhibitory circuits along these relay systems use gamma amino benzoic acid (GABA) or glycine. Numerous studies in experimental animals have implicated glutamatergic neurotransmission in toxicity associated with trauma, ischemia/reperfusion, and epilepsy. Experimental inhibitors of the glutamatergic system are being investigated as therapy for brain injury.15 GABA is synthesized from glutamate by the action of glutamic acid decarboxylase (GAD). Impaired GABAergic transmission is involved in some forms of epilepsy, and autoantibodies against GAD are thought to be the cause of the spastic gait seen in horses with stiff-horse syndrome.16

Diffuse projection systems include cholinergic, dopaminergic, noradrenergic, serotonergic, and histaminergic neurons. These systems are targets for numerous drugs used for psychiatric and movement disorders in humans. Dysfunction of cholinergic neurotransmission is responsible for the signs of fluphenazine and metoclopramide reactions in horses.17

CLINICAL NEUROANATOMY
The remainder of this chapter is designed to group neurologic functions according to major areas of the CNS. It complements the information provided in Chapter 50.

Whole Brain
Level of Consciousness
One of the critical functions of the reticular formation of the brain stem is activation of the cerebral cortex for the awake state. This component of the formation, known as the ascending reticular activating system (ARAS), is an ill-defined meshwork of cells extending throughout the brain stem that receives afferent input from all parts of the CNS and projects excitatory stimuli cortically.

Lesions anywhere in the brain stem, whether they are focal or extensive, may reduce the level of consciousness, whereas cortical injury must be diffuse to cause noticeable obtundation. The ARAS is also involved in the initiation and maintenance of sleep. Abnormalities of production or action of hypothalamic arousal peptides (hypocretins/orexins)18 or imbalances of brain stem neurotransmitters may result in narcolepsy/cataplexy sleep disorders.

Upper Motor Neuron System (Voluntary Movement)
The upper motor neuron (UMN) system is responsible for the initiation of voluntary movement and regulation of posture through support against gravity.2 The latter is effected in part by modulation of the antigravity myotatic reflexes of the limbs. The component of the UMN system originating in the hypothalamus is responsible for the control of muscular activity associated with visceral functions (respiratory, cardiovascular, urinary).

Direct cortical influence over motor activity in the horse via the pyramidal system is largely limited to fine control of the muzzle and lips.2 The much more important extrapyramidal system is a multisynaptic pathway from the brain to the lower motor neurons of the spinal cord and brain stem. The frontal and parietal lobes of the cerebrum, basal nuclei,
diencephalon, midbrain, and hindbrain all contribute to the UMN system. Upper motor neurons, particularly those originating in the midbrain, are generally inhibitory to myotatic reflexes. Damage to the neurons or axons of these tracts, in the caudal midbrain, hindbrain, or spinal cord, increases extensor tonus and may result in limb spasticity (“stiffness”). With UMN injury there are also limb weakness, hyperactive extensor reflexes, and crossed extensor reflexes, all in the ipsilateral limbs.

Movement disorders are characteristic of UMN disease in the rostral brain stem. Abnormal involuntary movements include dystonia (writhing movements of the muscles of the head and spine), ballism (violent flailing of a limb), chorea (repetitive jerky movements of different muscle groups), and myoclonus (repetitive movements of a single muscle group).10 Nigropallidal encephalomalacia is a disease of this type in horses that is caused by the chronic consumption of yellowstar thistle or Russian knapweed plants.11 There is dystonia and rigidity of the muscles of the head resulting in lip retraction, tongue protrusion, and inability to prehend food. More generalized extrapyramidal syndromes in horses are reportedly associated with reactions to fluphenazine (an antipsychotic sedative drug) and metoclopramide (a prokinetic agent).

**Forebrain**

**Behavior (Limbic System, Temporal Lobes)**

Normal behavior requires integration of signals from the entire CNS, but it principally involves the forebrain. Most important in controlling intrinsic behavior is the limbic system, a connected series of structures in the cerebrum and diencephalon. A minor component is also found in the midbrain. Included are the amygdala, hippocampus, fornix, cingulate gyrus, and septal area. A closely associated region that is important in primate behavior is the temporal lobe of the cerebrum.2 It is thought that behavior based on conditioning and experience (i.e., learning) is controlled by the temporal lobes. Structural, metabolic, or psychological disturbances affecting these areas may result in behavioral abnormalities (i.e., dementia). Dementia can be defined as changes in normal habits, personality, attitude, or reaction to the environment, or loss of learned skills. Some of the signs that may be seen include disorientation in a familiar environment, failure to recognize a handler or object, loss of the ability to be led, frequent yawning, head-pressing, irritability, unprovoked kicking or biting, compulsive walking or circling, and dramatic changes in eating or drinking habits.

Almost any disturbance of the forebrain can potentially cause dementia. Encephalitis, head trauma, space-occupying lesion, malformation, infarct, and metabolic disorders all are likely to cause changes in behavior. Important examples in horses include rabies, eastern equine encephalomyelitis (EEE), leukoencephalomalacia, neonatal encephalopathy (neonatal maladjustment syndrome), cerebral abscess, cholesterol granuloma, frontal/parietal trauma, postseizure encephalopathy, hepatic encephalopathy, hyperammonemia, and hydrocephalus. It is likely that structural or metabolic forebrain disease is the cause of dementia if other neurologic abnormalities are found by neurologic examination or imaging studies. In the absence of such supportive findings, abnormal behavior such as self-mutilation20 may have a psychological basis.

**Seizures**

Seizures are sudden, transient attacks of abnormal motor or behavioral activity attributable to paroxysmal depolarization of part or all of the brain.9 Depolarization occurs either simultaneously throughout the brain or originates from a hyperirritable focus somewhere in the forebrain. Seizures originating from a focus are likely to initially have asymmetric clinical signs, and there may be additional signs of forebrain disease between seizures that are revealed by neurologic examination.

Seizures frequently originate in the frontal (motor) cortex and involve muscle fasciculations and tremors around the head or abnormal movements of the jaws and tongue (“chewing gum fits”). Convulsions characteristic of neonatal encephalopathy often are of this type. In their severest (grand mal) form, seizures manifest as sudden recumbency, with a brief phase of extensor tonus, followed by clonic (“galloping”) movements of the legs, loss of consciousness, and a variety of signs of autonomic discharge (e.g., sweating, urination, defecation, pupillary dilation). Mild motor seizures are often accompanied by behavioral signs such as obtundation, compulsive walking, hyperresponsiveness to stimuli, or other signs of dementia. Seizure foci in the forebrain may occur at sites of previous or current trauma or inflammation. Examples include skull trauma, equine protozoal myeloencephalitis (EPM), EEE, intracranial neoplasia, and aberrant parasite migration (see Table 49-3 for a more complete list). Causes external to the brain include hyperammonemia, hyponatremia, hyperthermia, and hepatic or renal failure. Juvenile epilepsy of Arabian foals occurs because of transiently increased susceptibility to seizures and manifests as repeated generalized seizures without other evidence of brain disease in foals 1 to 9 months old.9

**Perception of Pain (Parietal Cortex, Cranial Nerve V)**

Pain sensation is transmitted from the body to the brain in multisynaptic spinothalamic tracts.7 Signals initiated by stimulation of pain receptors on one side of the body pass through spinothalamic tracts on both sides of the spinal cord. Axons in these tracts course rostrally to terminate in the thalamus. From there, cell bodies project axons to the sensory (somesthetic) cortex for conscious perception of pain or other sensory modalities. It is thought that the somesthetic cortex is located principally in the parietal lobe of the cerebrum.

The pathways for pain perception in the head pass through the maxillary, ophthalmic, and mandibular branches of the trigeminal nerve. The central component of this pathway is predominantly contralateral. Unilateral lesions of the sensory parts of the forebrain (thalamus, internal capsule, sensory cortex) thus cause contralateral facial hypegesia. Because the central components of vision and facial pain perception are close anatomically, it is common to find unilateral facial hypegesia and blindness (on the same side) in the same horse.
Smell (Olfactory Bulbs, Cranial Nerve I)

Olfactory nerves pass through the cribriform plate and into the olfactory bulbs of the cerebrum. Information on smell is relayed through the thalamus to centers in the unconscious (limbic system) and conscious cerebrum.

Vision (Thalamus, Occipital Cortex, Cranial Nerve II)

In horses, 80% to 90% of optic nerve fibers from one eye cross at the optic chiasm, and 80% of fibers in the optic tracts synapse at the lateral geniculate nucleus in the thalamus. The remainder course to the midbrain to function in the pupillary light reflex (see later). Neurons in the lateral geniculate nucleus project via the internal capsule to the visual cortex in the occipital lobe of the cerebrum. This area is caudal in the cerebrum, immediately rostral to the tentorium cerebelli, and caudal to the parietal cortex. The pathway from the eye to the contralateral visual cortex via the optic nerve, lateral geniculate nucleus, and internal capsule must be intact for normal vision. Lesions in the pathway caudal to the optic chiasm result in blindness in the opposite eye, and lesions in the optic nerve rostral to the chiasm affect vision in the ipsilateral eye. Damage to the cortex should not affect the pupillary reflex pathway.

Visual perception is evaluated by obstacle tests (with and without blindfolding of one eye) and by the menace response. The menace response requires the central visual pathway just described plus normal facial nerve function. Integrity of the cerebellar cortex is also needed, although it is not known if the pathway that mediates this response actually passes through the cerebellum. It is important to note that the menace response does not develop in foals until they are 1 to 2 weeks old.

Any disease that causes diffuse, severe cerebral dysfunction is likely to cause blindness. Examples include EEE, postseizure encephalopathy, hyperammonemia, leukencephalomalacia, and frontal/parietal trauma. Asymmetric frontal/parietal skull trauma, EPM, cerebral abscess, and cholesterol granuloma are diseases that may cause unilateral visual deficits by affecting the forebrain on the opposite side. Arabian foals with cerebellar abiotrophy have normal vision, but menace responses are absent. 2

Midbrain

Pupillary Light Response, Pupil Size (Midbrain, Cranial Nerves II, III)

In the normal horse, pupil size reflects the balance of sympathetic (dilator) and parasympathetic (constrictor) influences on the smooth muscle of the iris. Preganglionic neurons for sympathetic supply to the head arise in the gray matter of the first four thoracic segments of the spinal cord, and they then course rostrally in the cervical sympathetic trunk. After synapse in the cranial cervical ganglion adjacent to the guttural pouch, the postganglionic sympathetic neurons continue to the smooth muscle of the orbit and act to cause pupillary dilation. Emotional and other influences on sympathetic pupillary tone are governed by hypothalamic centers that act through UMN tracts descending from the midbrain.

 Interruption of preganglionic or postganglionic sympathetic nerves to the eye causes Horner’s syndrome, with miosis of the pupil, enophthalmos, ptosis, and spontaneous sweating and vasodilatation over the side of the face. Injury to the sympathetic UMN tracts in the brain or spinal cord not only may cause Horner’s syndrome but also may result in increased sweating over the entire side of the body. Preganglionic neurons may be injured in the proximal thorax or along the neck in the vagosympathetic trunk. The
cranial cervical ganglion and postganglionic neurons may be destroyed by fungal invasion in horses with guttural pouch mycosis.\textsuperscript{22} Rarely, signs referable to interruption of sympathetic L MN tracts are found in horses with brain stem or spinal cord lesions (e.g., EPM, spinal cord trauma).

Parasympathetic preganglionic neurons arise in the midbrain and exit the skull in the oculomotor nerve (III). These neurons synapse behind the eye in the ciliary ganglion. Postganglionic neurons pass along the optic nerve to innervate the ciliary muscle and constrictor of the pupil. This system is responsive to the amount of light received by each eye. The afferent part of the pupillary light reflex passes via the optic nerves and optic tracts, past the thalamus, to terminate in the midbrain. There is extensive decussation of these tracts in both the chiasm and the midbrain, so light directed into one eye causes reflex pupillary constriction in both eyes.

Injury to an optic nerve renders the ipsilateral pupil unresponsive to direct light, but it remains responsive to light directed into the contralateral eye. In contrast, injury to the midbrain or oculomotor nerve causes mydriasis in the ipsilateral eye that is unresponsive to light directed into either eye. Focal diseases such as EPM, aberrant parasite migration, or midbrain hemorrhage could potentially involve the oculomotor nuclei, although this is rare. More commonly, the oculomotor nuclei depressions are compressed by swelling and subtentorial herniation of the cerebral hemispheres. Early in the process of cerebral injury, pupils are often miotic; progression to bilateral mydriasis is a grave prognostic sign.\textsuperscript{2}

\textbf{Midbrain/Hindbrain}

\textbf{Eye Position (Midbrain, Pons, Cranial Nerves III, IV, VI)}

From nuclei in the midbrain and pons, the oculomotor, trochlear, and abducens nerves exit the cranial cavity through the orbital fissure and ramify in the periorbital tissues to innervate the rectus and oblique muscles of the eye. The oculomotor nerve also supplies the levator palpebræ and pupillary constrictor muscles, and the abducens nerve innervates the retractor bulbii muscle. Lesions in these nerves (or nuclei) cause abnormal eye position (strabismus). The direction of eye deviations resulting from specific nerve lesions is not known for the horse and cannot necessarily be inferred from data for other species.\textsuperscript{9} Unlike vestibular strabismus, which can be corrected by rotating the head (usually in the direction of the lesion), strabismus caused by lesions in extraocular nerves persist in any head position. The finding of mydriasis (III) or defective eyeball retraction (VI) may provide additional information on lesion location in horses with strabismus.

\textbf{Hindbrain}

\textbf{Mastication (Pons, Cranial Nerve V)}

The lower motor neurons of the trigeminal nerve arise in the pons and pass through the petrous temporal bone and the foramen ovale adjacent to sensory trigeminal neurons and are distributed to the muscles of mastication: masseters, pterygoids, temporals, and rostral digastrics.

With unilateral damage to the trigeminal nucleus (or nerve), there is deviation of the lower jaw toward the normal side. By 2 weeks after injury, there is obvious muscular atrophy. Bilateral severe involvement of the trigeminal nuclei (or nerves) causes a dropped jaw, weak jaw tone, slight tongue protrusion, and inability to prehend or chew feed. Damage to the nucleus of V, either unilaterally or bilaterally, is found in some horses with EPM.\textsuperscript{23}

\textbf{Facial Expression and Movement (Medulla, Cranial Nerve VII)}

Normal facial tone, expression, and movements are dependent on the integrity of the facial nerves. These nerves arise from nuclei in the rostral medulla (hindbrain) and exit the calvarium with cranial nerve VIII via the internal acoustic meatus. The nerve courses through the facial canal in the petrous temporal bone adjacent to the middle ear and emerges through the stylomastoid foramen. The facial nerve is distributed to the muscles of facial expression, including those of the ear, eyelid, nose, and lips, and the caudal belly of the digastic muscle.

The effects of interruption of this motor pathway depend on the site of damage. With involvement of the nucleus or proximal nerve, there is drooping of the ear and lip, ptosis, and collapse of the nostril, and the muzzle is pulled toward the normal side. Saliva often drools from the affected side of the mouth, and the horse has difficulty prehending food, especially grain. There may be exposure keratitis secondary to eyelid paralysis.

The facial nerve also contributes parasympathetic neurons to lacrimal glands (and some salivary glands). Damage to the facial nerve proximal to the middle ear is likely to affect tear production by this mechanism. Tear production can be measured and compared between sides using the Schirmer tear test. The sensory component of the facial nerve contains fibers from the tongue (taste) and middle ear.

Facial nerve motor function is evaluated by testing “flick” reflexes of the lip, eyelid and ear. These reflexes involve afferent sensory input via trigeminal neurons that terminate in the medulla on the lower motor neurons (L MNs) of the facial nerves. Note that these reflexes do not involve the forebrain and can thus occur without conscious perception. Because they are close together in the hindbrain and skull, the facial and vestibulocochlear nerves are often damaged together. Diseases that often affect both nerves include those that are central (West Nile virus encephalomyelitis, EEE, EPM, and migrating parasite) and those that are peripheral (polineuritis equi, lightning strike, petrous temporal bone fracture, temporohyoid osteoarthropathy, and extramedul- lary neoplasm). To distinguish clinically between central and peripheral causes, it is important to look for other signs of brain disease. For example, a horse with a lesion in the medulla affecting the nuclei of cranial nerves VII and VIII may also be obtunded with weakness and ataxia of the ipsilateral limbs.

\textbf{Balance and Equilibrium, Hearing (Medulla, Cranial Nerve VIII)}

The vestibular system is responsible for orientation of the horse relative to gravity (Fig. 49-5). The receptor is in the bony labyrinth of the inner ear. The membranous labyrinth includes three semicircular ducts containing endolymph
that connect to vestibular nerve endings at the cristae ampullares. Vestibular neurons pass centrally through the internal acoustic meatus to penetrate the rostral medulla and terminate in four vestibular nuclei. These nuclei have numerous projections to the nuclei controlling extraocular muscles, the cerebellum, and the trunk and limbs (vestibulospinal tracts).

The vestibular system controls the conjugate movements of the eyes during movement of the head through extensive connections with the nuclei of cranial nerves III, IV, and VI. Vestibular-cerebellar pathways pass through the caudal cerebellar peduncle. These pathways function to smoothly coordinate the movements of the eyeballs, trunk, and limbs with those of the head. Vestibulospinal tracts descend ipsilaterally to synapse on the LMNs and facilitate extensor muscles of the limbs while inhibiting flexor muscles. Some vestibulospinal tracts cross and reduce extensor tonus in contralateral limbs.

Unilateral disease involving the peripheral part of the vestibular system causes asymmetric ataxia with preservation of strength. The poll rotates toward the side of the lesion, and the head and neck may be turned toward the lesion. The body leans, falls, or rolls toward the side of the lesion, and the horse may stagger in tight circles. This type of circling should be distinguished from the compulsive walking in circles (without head tilt) that is characteristic of horses with asymmetric frontal cerebral lobe lesions. Because there is some visual compensation for vestibular ataxia, blindfolding exacerbates the signs and is a useful clinical test in mild cases of suspected vestibular disease.

In horses with central vestibular disease, there are usually additional signs of hindbrain disease (e.g., depression and limb weakness), and head tilt may be either toward or away from the side of the lesion. The latter presentation is known as paradoxical central vestibular disease and usually follows involvement of vestibular connections within the cerebellum. Unilateral vestibular disease often causes spontaneous or positional nystagmus, and physiologic (vestibular) nystagmus may be absent or abnormal. In peripheral disease, the nystagmus is always horizontal, rotatory, or arc shaped, with the fast phase away from the lesion. With central involvement of the vestibular system, nystagmus also may be vertical. Typically, the eye on the affected side rotates ventrally in the orbit while the eye on the normal side rotates dorsally (especially when the head is extended). This abnormal eye position is termed vestibular strabismus. Bilateral vestibular disease is characterized by severe symmetric ataxia and wide, sweeping movements of the head from side to side. In addition to the diseases described earlier that also affect the facial nerve, an idiopathic vestibular syndrome is reported to occur in the horse, possibly as a result of viral neuritis or labyrinthitis.9

Neurons of the cochlear division of cranial nerve VIII pass from receptors in the middle or inner ear to auditory centers in the midbrain and thalamus. A variety of local reflexes are initiated by stimulation of the cochlear nerve. In addition, there is projection of conscious pathways for hearing from the thalamus to the cortex (temporal lobe?). Deafness is rarely detected in the horse.

**Taste (Cranial Nerves VII, IX, X)**

Taste buds are found on the surface of the tongue and also in the soft palate, pharynx, lips, and cheeks. Sensory gustatory innervation is provided by the facial nerve (rostral two thirds of the tongue), glossopharyngeal nerve (caudal one third of the tongue), and vagus (pharynx and palate). General sensory innervation provided by the trigeminal nerve probably also contributes gustatory information. Perception of taste involves the forebrain, including the limbic system. Deficiencies in the sense of taste are very difficult to detect by clinical testing.

**Movement of Pharynx and Larynx (Cranial Nerves IX, X, XI)**

Motor innervation of the larynx and pharynx originates in neurons in the nucleus ambiguus, a fusiform structure extending the length of the medulla. This nucleus provides axons for the glossopharyngeal, vagus, and spinal accessory (internal branch) nerve roots. These roots form nerves that innervate the soft palate, pharynx, larynx, and cranial esophagus via the pharyngeal plexus and cranial and recurrent
laryngeal nerves. The nucleus ambiguus is continued in the spinal cord as the nucleus of the external branch of the spinal accessory nerve (innervation of trapezius and parts of brachiocephalicus and sternocophalicus). The facial and hypoglossal nerves innervate several of the muscles that control movements of the hyoid apparatus; therefore, impaired movement of the hyoid apparatus caused by paral-ysis of these nerves could affect movements of the larynx and pharynx. Clinically, such effects are minor in horses at rest but can be revealed by intense exercise.

Unilateral (hemiplegia) or bilateral pharyngeal paralysis interfere with swallowing and manifests as signs of dysphagia: coughing and gagging during eating with return of saliva, feed, and water through the nostrils and mouth. With complete unilateral laryngeal hemiplegia (i.e., para-lysis of adductors and abductors), there is exercise-induced respiratory stridor and aspiration of feed into the trachea. In horses with bilateral laryngeal paralysis, inspiratory stridor occurs at rest and there is aspiration pneumonia. Some to all of these pathways can be affected peripherally in horses with botulism, guttural pouch mycosis, extramedullary neoplasia, or basilar skull fracture. Examples of diseases affecting the hindbrain that may cause laryngeal or pharyngeal dys-function are EEE, EPM, leukoencephalomalacia, bacterial meningitis, and West Nile viral encephalomyelitis.

**Tongue Movement (Cranial Nerve XII)**
The muscles affecting movement of the tongue are supplied by the hypoglossal nerve. Neurons of the hypoglossal nerve originate in the hypoglossal nucleus in the caudal aspect of the medulla and emerge from the medulla as a horizontal row of rootlets, which combine to form the nerve as it enters the hypoglossal foramen. After emerging from this foramen, the hypoglossal nerve runs forward and ventrally in association with the gullett pouch myosis, extramedullary neoplasia, or basilar skull fracture. Tongue hemiplegia and atrophy has been seen in horses with EPM, although any cause of caudal hindbrain disease can damage the hypoglossal nuclei.

**Cerebellum**
The cerebellum sits in the caudal fossa of the skull and is separated from the cerebral hemispheres by the tentorium cerebelli. It is divided into the flocculonodular lobe, also known as the vestibular cerebellum, and the much larger body of the cerebellum. The cerebellar body consists of a median region, the vermis, and two lateral cerebellar hemispheres. Connections with the rest of the CNS are via three peduncles: efferent connections pass through the rostral peduncle and afferent pathways enter the cerebellum via the middle and caudal peduncles.

The cerebellum regulates and smooths motor activity initiated by the UMN system. It also acts to maintain equi-librium and appropriate body posture during rest and motion. Proprioceptive information is gathered via afferent connections from the spinal cord (spinocerebellar tracts) and vestibular system and senses UMN activity via extensive connections with brain stem UMN nuclei (including the olivary nuclei). Efferent cerebellar neurons project to vestibular nuclei and other parts of the brain stem including the thalamus. There is virtually no projection of cerebellar efferents into the spinal cord.

Cerebellar disease is usually diffuse and manifests as symmetric ataxia without weakness. There is defective regulation of the rate, range, and force of movement. Limbs may appear spastic with excessive (hypermetric) or inadequate (hypometric) flexion during protraction. Signs are most obvious when there is a change in the force or direction of voluntary movement. At rest, the body may sway, laterally or backward and forward, and there may be coarse head bobbing or tremor that is exacerbated by voluntary move-ment, such as reaching the head out for food. Extensor muscle tone is increased and limb reflexes may be hyper-active. With diffuse cerebellar cortical disease, the menace response is absent, although vision is normal (see p. 636).

Signs of diffuse cerebellar disease are seen in Arabian horses or Götland pony foals with cerebellar abiotrophy. This inherited disease manifests at any time from birth to 3 months of age and may be stable or progressive for weeks to months. Rarely, horses with poll trauma have a head bob indicating cerebellar injury. The rhabditid nematode *Halicephalobus gingivalis* has a propensity to invade the caudal fossa and cause cerebellar destruction. Tremorgenic mycotoxins produced by parasitized perennial ryegrass or *Paspalum* species cause signs suggestive of cerebellar dysfunc-tion, although other parts of the CNS are also affected.

**Spinal Cord**

**Upper Motor Neuron (Muscle Tone and Voluntary Movement)**

Axons of the UMN extrapyramidal and vestibular systems travel from cell bodies throughout the brain and pass predominantly in reticulospinal and vestibulospinal tracts to LMN in the ventral and intermediate columns of the gray matter of the spinal cord. As described previously (see "Upper Motor Neuron System" under "Whole Brain"), this system provides tonic support for the body against gravity and recruits spinal reflexes for the initiation of voluntary movement. UMMs act by influencing α and γ motor neu-rons in the spinal cord. These LMMNs, in combination with afferent nerves and stretch receptors in the neuromuscular spindles and tendons, control muscle tone and movement by myotactic and antymotactic reflexes. Most descending UMN tracts are inhibitory to extensor motor neurons. Removal of these influences by transection through the midbrain causes extension of head, neck, trunk, and limbs, signs that are characteristic of decerebrate rigidity. Basic locomotor activity involves recruitment and control of these reflexes by distinct postural and voluntary UMN systems.

Interruption of UMN tracts in the spinal cord causes signs of ipsilateral weakness of the trunk and limbs. Signs of paresis range in severity from slight toe-dragging and
delayed protraction, to recumbency and inability to rise. Because myotatic reflexes are released from inhibitory UMN influences, there may also be spasticity (stiffness) of limb movement. This is most obvious in the thoracic limbs, which may appear to float during walking. The stiff appearance reflects decreased flexion of the limb during the protraction phase of the stride. Interference with UMN may also manifest as delayed initiation of voluntary movement or alterations in gait cadence. For example, some horses with spinal cord disease may have a lateral "pacing" gait at walking speed. If LMNs are not affected, spinal reflexes (e.g., patellar) are either normal or exaggerated on the side of the spinal cord lesion, and crossed extensor reflexes may be seen. It should be noted that crossed extensor reflexes are normal in newborn foals.9

Spastic paresis is especially common with focal compression of the cervical spinal cord in horses with cervical stenotic myelopathy (CSM) or spinal cord trauma. Other significant causes of LMN disease (in the spinal cord) include EPM, equine degenerative myeloencephalopathy, spinal cord abscess or tumor, and aberrant parasites migration. In keeping with the basic principles of neuroanatomic localization, UMN lesions from C1 to T2 (inclusive) may cause neurologic signs in all four limbs, lesions from T3 to S2 can only affect the pelvic limbs, and lesions caudal to S2 do not directly affect gait. With external compression of the cervical spinal cord (as in CSM), signs are typically worse in the pelvic limbs than in the thoracic limbs. The principles of neuroanatomic localization of spinal cord lesions are discussed more fully in Chapter 50.

Lower Motor Neuron and Spinal Cord Reflexes

The function of the CNS is exerted entirely through the actions of LMN on striated (skeletal) and smooth muscle. Lower motor neurons to skeletal muscles are found in the ventral columns of the gray matter, whereas those of the autonomic nervous system are located in the intermediate columns. In the horse, there are 8 cervical, 18 thoracic, 6 lumbar, 5 sacral, and a variable number of coccygeal (caudal) spinal cord segments. LMNs originating in the gray matter of a segment form a ventral root, which then exits the vertebral canal through the intervertebral foramen of the vertebra of the same name. The ventral root joins with the dorsal sensory root to form the segmental spinal nerve. In the cervical vertebrae, this foramen is at the cranial end of each vertebra. For the remaining roots, the foramina are at the caudal end. The more caudal spinal cord segments have long nerve roots because the spinal cord segments are shifted cranially with respect to the vertebrae. The first three sacral segments are in the 6th lumbar vertebra, and the spinal cord ends within S2.2

The LMNs form the efferent part of spinal reflexes, which are central to the neurologic examination and the process of neuroanatomic localization. The neurons of the afferent (sensory) component of reflexes course from receptors in the skin, muscle, or tendon, through the spinal nerve and dorsal root, into the dorsal horn of the gray matter, where they terminate on interneurons. The interneurons then complete the pathway by passing to the LMN. An exception to this is the patellar reflex, wherein the sensory neuron terminates directly on the LMN in the ventral horn. Long (i.e., multisegment) spinal cord reflexes, including "slap" tests, cervicofacial and cutaneous trunci reflexes, and caudal reflexes, including anal and tail-clamp, are routinely evaluated during neurologic examination. Limb reflexes, including withdrawal, patella, and triceps, are always evaluated in neonatal foals and in older horses that are recumbent. The specifics of individual spinal cord reflexes are covered in Chapter 50.

Abnormalities of LMN (in gray matter, ventral root, peripheral nerve, or neuromuscular junction) manifest as flaccid muscle weakness (paresis, paralysis) with hypotonia and hyporeflexia. Within 1 to 2 weeks, muscle atrophy is noticeable, and this neurogenic muscle atrophy progresses rapidly.2 Note that neurogenic atrophy is a consequence only of LMN disease; UMN involvement results in weakness without atrophy. Ventral nerve roots contribute to multiple peripheral nerves, and peripheral nerves are derived from multiple roots, so injury to gray matter of an individual segment or to a ventral nerve root produces less severe neurologic signs than does loss of function in a peripheral nerve.2 Examples of conditions that affect the LMN in horses are botulism (neuromuscular junction), trauma, ischemia associated with recumbency, neuritis of the cauda equina/polyneuritis equi, EPM, postanesthetic myelomalacia, and equine motor neuron disease.

Proprioception

Through a system of receptors in muscles, tendons, and joints, the general proprioceptive system is able to monitor the position of the body or limbs in space. Proprioceptive information is passed centrally in sensory nerves that terminate in the dorsal gray column on cell bodies of neurons in the spinocerebellar tracts. These tracts pass cranially and provide information for the cerebellum to use in its role of regulating posture, muscle tone, locomotion, and equilibrium. Other proprioceptive pathways pass from the spinal cord to the somesthetic sensory cortex via relay nuclei in the midbrain and thalamus.

Interruption of spinal cord proprioceptive pathways interferes with recognition by the brain of the positions in space of the body and limbs. This is manifest as ataxia (incoordination). Signs of proprioceptive deficit in the horse include base-wide or base-narrow limb placement, swaying of the trunk and torso during walking (but not usually at rest), and overstriding, especially in the pelvic limbs. During circling, limb ataxia is evident as circumduction in the pelvic limbs and interference in the thoracic limbs.

Urination

Parasympathetic LMNs to the bladder’s smooth muscle (detrusor) originate in the intermediate column of the gray matter of sacral segments 2 to 4. These neurons exit in ventral roots and contribute to the pelvic plexus, a network that supplies autonomic innervation to the smooth muscle of the bladder and rectum. Sympathetic LMNs to the bladder begin in the gray matter of L1-4, exit the vertebral canal, and course to the pelvic plexus. Postganglionic sympathetic neurons terminate on smooth muscle in the body.
and neck of the bladder and proximal urethra. These autonomic LMNs function in local reflexes. Afferent neurons pass from stretch receptors in the bladder wall and enter the spinal cord in dorsal sacral nerve roots to exert inhibitory influences on parasympathetic and sympathetic LMNs. Striated muscle of the urethra is innervated by somatic LMNs in the pudendal nerve. Urination occurs when there is stimulation of parasympathetic nerves to the detrusor muscle, inhibition of sympathetic nerves to the detrusor muscle, and inhibition of sympathetic and somatic nerves to the urethra. The net effect of this activity is contraction of the smooth muscle of the body of the bladder and relaxation of the proximal urethra. Centers in the midbrain and hindbrain receive sensory information from the bladder and modulate reflex activity via UMNs passing caudally in the spinal cord. Forebrain influence on these centers is responsible for initiation of voluntary voiding.

In horses with severe spinal cord disease cranial to S2, there may be loss of voluntary control of urination. Within 2 weeks, "spinal reflex bladder" function develops, which results in intermittent voiding with retention of small amounts of urine. Horses with severe CSM, EPM, vertebral trauma, or epidural abscess may be presented in this way. When there is a spinal cord lesion between L4 and S2, reflex pathways for inhibition of sympathetic activity may be interrupted, resulting in increased urethral tone and functional obstruction of urinary outflow. This is the case in some horses with equine herpesvirus-1 (EHV-1) myeloencephalopathy, although others have signs of LMN bladder (see later). 26

With injury to the sacral spinal cord segments or nerves, the bladder and urethra are atomic and distended and there is overflow incontinence. Although a small amount of intrinsic reflex bladder contraction ("automatic bladder") may occur, it is ineffectual, and large volumes of urine and sediment remain. Trauma, epidural abscess or tumor, EHV-1 myeloencephalopathy, sorghum–Sudan grass toxicity, and neureitis of the cauda equina are diseases that can cause these signs. Idiopathic atomic bladder (also known as sabulous cystitis) is found in middle-aged geldings and some stallions and resembles the presentation of horses with cauda equina syndrome; however, the idiopathic syndrome does not appear to be caused by denervation of bladder muscle, and there are no other signs of cauda equina syndrome. In cases of LMN urinary incontinence, additional nonurinary signs of sacral nerve injury are expected. These are the signs of cauda equina syndrome and include fecal incontinence, paralysis of the anus, tail, and penis, and perineal analgesia.

**Defecation**

The smooth muscle of the rectum and anus is innervated by postganglionic parasympathetic neurons in a way that parallels that described for the bladder. Innervation of striated muscle of the anus is provided by the pudendal nerve. Spinal cord lesions cranial to S2 are unlikely to affect defecation; however, involvement of the sacral segments results in rectal obstruction and may cause colic. Diseases causing rectal paralysis are the same as those described under "Urination," earlier.

**Sensation**

Sensory information from pain, thermal, and touch receptors is conveyed to the spinal cord by peripheral nerves, spinal nerves, and dorsal roots. Branches pass several segments both cranially and caudally from the site of spinal cord penetration and terminate on spinthalamic neurons or interneurons involved in spinal reflexes. Spinthalamic pathways servicing a single dorsal nerve root course cranially on both sides of the spinal cord. Pain perception requires interpretation of afferent information by the forebrain and has already been described. The flexor (withdrawal) reflexes require only sensory nerves, contiguous spinal cord segments, and LMNs. In the thoracic limbs, spinal cord segments C6 to T2 are required, and L6 to S2 are involved in the pelvic limb reflex. Evaluation of sensation over the trunk and limbs requires knowledge of the common autonomous zones for sensory nerves. This will be described in more detail in Chapter 54.

NEUROLOGIC EXAMINATION
A competent neurologic examination is not unlike an evaluation for lameness, where the initial evaluation is by systematic, “passive” examination and this is followed by an assessment of the gait. This chapter contains a description of an ordered approach to neurologic examination (Box 50-1 is a summary). There is considerable emphasis on evaluation of symmetry during each element of the examination. To accurately assess symmetry, it is essential that a mirror-image technique be used when comparing sides—that is, if the right hand of the examiner is used to test one side, the left hand should be used for testing the opposite side. The only equipment needed is a transilluminator, a hemostat, and a patella hammer (for neonatal examinations). The findings are used to localize a lesion or lesions. This is the basis for formulation of an initial rule-out list and for planning additional diagnostic tests.

In this discussion, all abnormal findings are interpreted in the context of a neurologic explanation. It is clear that many of these signs could be caused by lesions outside the nervous system. Full general physical and lameness examinations should also be performed to assess possible involvement of other body systems.

Mentation
Alertness and behavior are not evaluated by specific testing but are assessed from the history and general observation throughout the examination.

Alertness
Assess level of consciousness or alertness on a continuous scale from normal (i.e., bright and alert) to comatose. Progressive levels of obtundation are termed lethargy, stupor, semicoma, and coma. With lethargy, there is a somewhat blank facial expression with slight drooping of the ears and eyelids, sluggish responsiveness to stimuli, and reduced voluntary activity. It should be noted that some conditions cause horses to lose facial expression while maintaining normal alertness. Botulism is a disease of this type. A stuporous horse stands in one place with the head held low and responds only to strong stimuli. Stuporous horses that are recumbent are defined as semicomatose, and recumbent horses that do not respond to any stimulus are comatose.

Some horses with reduced alertness appear irritable and anxious, walk compulsively, or otherwise interact abnormally with handlers. An obtunded horse showing such behavior may be termed delirious.

It is very unlikely that a horse with narcolepsy will have a sleep attack while being examined; thus, assessment of possible narcolepsy usually rests on description by the owner or video recordings of an attack. Occasionally, neonatal foals collapse during examination and briefly appear comatose. These are typically benign episodes of cataplexy and are probably an exaggerated version of the collapse response by which a normal foal can be cast into recumbency.

Behavior
Abnormalities of behavior are termed dementia. Behavior is assessed from history and general observation in the course of the examination. Typical abnormal behaviors resulting from central nervous system (CNS) disease include self-mutilation, head-pressing, compulsive walking (often in a circle), yawning, aggression (including unprovoked biting or

NEUROLOGIC EXAMINATION
A competent neurologic examination is not unlike an evaluation for lameness, where the initial evaluation is by systematic, "passive" examination and this is followed by an assessment of the gait. This chapter contains a description of an ordered approach to neurologic examination (Box 50-1 is a summary). There is considerable emphasis on evaluation of symmetry during each element of the examination. To accurately assess symmetry, it is essential that a mirror-image technique be used when comparing sides—that is, if the right hand of the examiner is used to test one side, the left hand should be used for testing the opposite side. The only equipment needed is a transilluminator, a hemostat, and a patella hammer (for neonatal examinations). The findings are used to localize a lesion or lesions. This is the basis for formulation of an initial rule-out list and for planning additional diagnostic tests.

In this discussion, all abnormal findings are interpreted in the context of a neurologic explanation. It is clear that many of these signs could be caused by lesions outside the nervous system. Full general physical and lameness examinations should also be performed to assess possible involvement of other body systems.

Mentation
Alertness and behavior are not evaluated by specific testing but are assessed from the history and general observation throughout the examination.

Alertness
Assess level of consciousness or alertness on a continuous scale from normal (i.e., bright and alert) to comatose. Progressive levels of obtundation are termed lethargy, stupor, semicoma, and coma. With lethargy, there is a somewhat blank facial expression with slight drooping of the ears and eyelids, sluggish responsiveness to stimuli, and reduced voluntary activity. It should be noted that some conditions cause horses to lose facial expression while maintaining normal alertness. Botulism is a disease of this type. A stuporous horse stands in one place with the head held low and responds only to strong stimuli. Stuporous horses that are recumbent are defined as semicomatose, and recumbent horses that do not respond to any stimulus are comatose. Some horses with reduced alertness appear irritable and anxious, walk compulsively, or otherwise interact abnormally with handlers. An obtunded horse showing such behavior may be termed delirious.

It is very unlikely that a horse with narcolepsy will have a sleep attack while being examined; thus, assessment of possible narcolepsy usually rests on description by the owner or video recordings of an attack. Occasionally, neonatal foals collapse during examination and briefly appear comatose. These are typically benign episodes of cataplexy and are probably an exaggerated version of the collapse response by which a normal foal can be cast into recumbency.

Behavior
Abnormalities of behavior are termed dementia. Behavior is assessed from history and general observation in the course of the examination. Typical abnormal behaviors resulting from central nervous system (CNS) disease include self-mutilation, head-pressing, compulsive walking (often in a circle), yawning, aggression (including unprovoked biting or...
kicking), timidity, loss of affinity of a foal for its dam, and loss of learned behaviors and skills. Inability or refusal of a trained horse to follow when being led is a form of dementia that may be obvious during neurologic examination.

**Lesion Location**

Obtundation reflects damage anywhere in the brain stem or diffusely in the cerebrum. Dementia is a sign of forebrain damage.

**Associated Clinical Signs**

Limb ataxia or weakness and signs of cranial nerve dysfunction are common in horses with obtundation secondary to brain stem disease. Compulsive turning of the head and neck in one direction, blindness, and seizures are other signs of forebrain dysfunction that may be seen in demented horses.

**Orientation and Coordination of the Head Examination**

Evaluate the orientation of the head from directly in front. Any head tilt is described from the patient’s perspective; thus, if the poll is rotated to the horse’s left (i.e., clockwise from the examiner’s point of view), the abnormality is described as a left head tilt. Repeatedly straighten and release the horse’s neck and head and observe whether or not the head returns to one side. Asymmetric disease of the vestibular system causes the head to tilt and turn, whereas asymmetric cerebral disease may cause the head and neck to turn without tilting. Carefully blindfold the horse and observe the effect on head position (Fig. 50-1). Blindfolding removes visual input to head position and exacerbates abnormalities caused by either vestibular or cerebral disease. Observe the head and neck from the side. Persistent horizontal or low position of the head may indicate neurologic or muscular weakness of the neck, whereas extended head position may be found in horses with upper cervical vertebral problems or guttural pouch disease. Offer feed or a treat to the horse and observe the way in which the horse moves its head in response. Horses with cerebellar disease often make jerky or bobbing movements of the head as they move toward the offered feed.

**Lesion Location**

Head tilt suggests involvement of the vestibular labyrinth, nerve, or root peripherally, or the vestibular nuclei and connections in the medulla oblongata or cerebellum centrally. It has also been suggested that lesions in the proximal cervical nerves may cause signs suggestive of vestibular disease. If the head is turned without tilting, involvement of the cerebrum is likely. Coarse or fine head bobbing, especially intentional, indicates diffuse cerebellar dysfunction.

**Associated Clinical Signs**

Because of the close association of cranial nerves VII and VIII, facial paralysis is often seen in horses with vestibular disease. With peripheral vestibular disease, there often is
spontaneous horizontal or arc-shaped nystagmus with the fast phase directed away from the side of the lesion. In horses with involvement of the central components of the vestibular system, there may be horizontal or vertical nystagmus. Damage to adjacent structures in the hindbrain may additionally cause obtundation, other signs of cranial nerve dysfunction such as dysphagia and masseter atrophy, and weakness or ataxia of the limbs on the side of the lesion. Horses with cerebellar cortical disease may lack menace responses despite having normal vision.

Muscles of Mastication

Examination

If the mouth hangs open and the tongue protrudes, there is probably bilateral paresis of the muscles that close the jaw (temporalis, masseter, and pterygoid). Grasp the upper and lower jaws at the level of the interdental space and attempt to pull the lower jaw downward. The jaws pull apart easily in horses with bilateral paresis of the masticatory muscles. Tuck the forelock behind one of the ears and compare the temporalis muscles from in front of the horse. Asymmetry may indicate neurogenic atrophy of the smaller side (Fig. 50-2). Turn the head from side to side and observe and palpate the masseter muscles. The pterygoid muscles and cranial belly of the digastricus muscle (the only muscle innervated by cranial nerve V that is devoted to opening the jaws) are located on the medial side of the mandible, so they are not readily palpable; however, atrophy of the pterygoids on one side is often evident as relative deepness of the supraorbital fossa on the same side. Peel back the upper and lower lips and examine the alignment of the symphyses of the upper and lower jaws. With acute unilateral paresis of the masticatory muscles, even before atrophy is apparent, the lower jaw may be deviated toward the normal side (see Fig. 50-2).

Lesion Location

Weakness or atrophy of the muscles of mastication indicates involvement of the motor division of the trigeminal nerve, its roots, or the trigeminal motor nucleus in the pons.

Associated Clinical Signs

Injury to the proximal part of the trigeminal nerve may also affect the sensory component, resulting in reduced facial sensation (hypalgesia) over one side of the face. With trigeminal damage at the level of the pons, there may be additional signs of hindbrain disease, such as obtundation, other signs of cranial nerve involvement (e.g., dysphagia, head tilt, or facial paralysis), and weakness and ataxia of the limbs on the same side.

Facial Tone

Examination

Examine the head carefully for symmetry of facial expression, particularly with respect to the ears, eyes, and muzzle. With complete unilateral facial paralysis, there is drooping of the ear, upper eyelid (ptosis), and lower lip, and immobility, narrowing, and lengthening of the affected external naris (Fig. 50-3). The muzzle is deviated away from the affected side, and saliva may drool from the mouth. Any or all of these components can be affected separately. Next, evaluate facial nerve function by testing "flick" reflexes on each side of the face. Each of these reflexes requires intact trigeminal sensory branches, central connections in the hindbrain, and functioning facial nerves. To test these reflexes, touch in turn the commissure of the lips, the medial and lateral canthi of the eye and the supraorbital fossa, and the ear. Appropriate responses are retraction of the commissure of the lip, blinking of the eye, and flick of the ear, respec-

Figure 50-2. Atrophy of the muscles of mastication in a horse with equine protozoal myeloencephalitis. Beginning about a month after foaling, this 11-year-old Thoroughbred mare had an insidious onset of ataxia and limb weakness. A, Six weeks later, ataxia and weakness were worse, especially in the left limbs, and there was obvious atrophy of the masseter and temporalis muscles on the right side. B, The lower jaw was deviated away from the affected side.
tively. It is helpful to have the handler cover the ipsilateral eye during testing of the lip and ear.

Test facial innervation of lacrimal glands by performing Schirmer tear tests. If tear production is reduced to less than 50% of normal on the side of the face that is paralyzed, there is likely to be a lesion affecting secretomotor fibers proximal (central) to the middle ear. Further test the symmetry of facial tone by using the thumbs or fingers to assess resistance simultaneously on both sides to retraction of lip commissures, elevation of upper eyelids, and forward extension of the ears. Examine the throat latch area. If there has been facial paralysis for more than 2 weeks, there usually is an obvious subcutaneous depression running ventrally from the base of the ear along the back of the mandible. This reflects atrophy of the parotidoauricularis muscle. Finally, test the cervicofacial reflex (see later) as part of the examination of long spinal reflexes. If there is obvious asymmetry of response, test cutaneous sensation at multiple locations over the face by pinching the skin with hemostats.

Associated Clinical Signs
Commonly there is also head tilt and spontaneous nystagmus because of involvement of the vestibular system. In horses with facial paralysis caused by brain disease, there may be other signs of hindbrain disorder such as obtundation, signs of abnormal cranial nerve function, such as dysphagia or masseter atrophy, or limb ataxia and weakness on the same side as the lesion. Nonneurologic signs include keratitis sicca (worse if tear production is reduced) and inspiratory stridor during exercise.

Facial Sensation
Examination
The sensory branches of the trigeminal nerve have already been tested as flick reflexes of the lip, eye, and ear. While standing in front of the horse, place the palm of the right hand on the muzzle, work the thumb into the right nostril, and touch the nasal septum on that side. In mirror-image fashion, use the left thumb to stimulate the left side of the septum. The normal response to this noxious stimulus is vigorous movement of the head away from the side of the stimulus. Compare the intensities of the response on each side. If there is obvious assymetry of response, test cutaneous sensation at multiple locations over the face by pinching the skin with hemostats.

Lesion Location
The pathway for recognition of this noxious stimulus is input through the sensory division of the trigeminal nerve to the pons and thence to the somesthetic area of the contralateral cortex. If flick reflexes are normal, a reduced or absent response to a noxious stimulus suggests involvement of the contralateral forebrain, probably at the level of the parietal cortex. In contrast, hypalgesia and hyporeflexia of flick reflexes of part to all of one side of the head indicates involvement of the trigeminal nerve or branches.

Associated Clinical Signs
Cortical blindness, obtundation, and abnormal behaviors may be seen when hemifacial hypalgesia is a result of forebrain disease. Peripheral lesions of the trigeminal nerve may involve motor fibers and result in weakness and atrophy of masticatory muscles.

Menace Response
Examination
Test menace responses while standing in front of the horse. Use the palm of the hand to make a threatening gesture toward the eye. Test from both temporal and nasal directions on each side. Stimulate the horse just before each menace gesture by tapping the skin below the eye. For safety reasons, always hold the noseband of the halter with one hand while using the other for testing. A normal menace
response is blinking of the eye, sometimes accompanied by
evasive movement of the head and neck. Compare carefully
the intensity of the menace responses elicited from each
side. In this regard, menace should be considered a quan-
titative response. Unlike simple reflexes, which are assessed
as present or absent, a menace response can be considered
abnormal if it is less vigorous than that elicited from the
opposite (normal) side.

Lesion Location
The menace response can be interrupted anywhere in its
pathway from the eye via the optic nerve to the contralateral
optic tract, diencephalon, internal capsule, and visual cortex.
From the visual cortex, the menace response pathway
continues to the facial nucleus and nerve on the side being
tested and receives essential input from the cerebellum.
If there is no other sign of cerebellar involvement, and if
facial nerve function and pupillary light reflexes are intact,
the lesion is contralateral, central to the optic chiasm, and
most likely in the forebrain. In normal neonates and in
older horses with diffuse cerebellar cortical disease, there
is no menace response, but the horse can see. In these
settings, vigorous threatening gestures toward the eye may
cause evasive movements of the head without blinking of
the eye.

Associated Clinical Signs
There may be other signs of asymmetric cerebral disease
such as compulsive walking in circles, dementia, head and
neck turn, obtundation, seizures, and facial hypesthesia on
the side opposite the lesion (i.e., the same side as the
defective menace). If the site of the lesion causing a menace
deficit is the optic nerve or fundus of the eye, the pupillary
light reflex on the same side should be abnormal. Head-
bobbing, dysmetria, and ataxia are expected in horses with
defective menace responses resulting from cerebellar dys-
function. If eyelid paralysis is preventing the menace response,
the palpebral (eyelid flick) reflex should also be abnormal
and there may be additional signs of facial paralysis.

Size of Pupils and Pupillary Light Reflex
Examination
If possible, examine the eyes in subdued or dim light so that
the pupils are large enough to easily allow appreciation of
reflex constriction. Stand in front of the horse while holding
the noseband of the halter and swing the light back and
forth from one side to the other so as to obliquely and
briefly illuminate each eye without causing constriction of
the pupils. Unequal pupillary size is termed anisocoria; a
constricted pupil is miotic, and a dilated pupil is mydriatic.
From this examination, determine whether or not the pupils
are of equal size and if the diameter of each pupil is appro-
priate for the conditions. In this way, refine the diagnosis of
anisocoria to miosis or mydriasis affecting a single eye.

Next, move closer to the horse and aim the light at the
skin below one eye. Redirect the beam directly into the eye.
This strong light should elicit both a dazzle reflex in the
ipsilateral eye and pupillary light reflexes (PLRs) in both
eyes. The dazzle response is an avoidance reaction to bright
light. There is blinking, retraction of the eyeball, and move-
ment of the head away from the light. A normal PLR is
immediate constriction of the pupils of both eyes in
response to light directed into one eye. If the direct (i.e.,
ipsilateral) pupillary light reflexes are normal on both sides,
no further testing is necessary. If one is abnormal, then
consensual (indirect) reflexes should be tested. To perform
the consensual reflex, watch the pupil in one eye while an
assistant shines the light into the opposite eye.

Lesion Location
The dazzle response is a subcortical reflex that is mediated
via afferent input through the optic nerve to regions of the
midbrain distinct from those required for the PLR and by
efferent output along the facial nerve. It is possible for a
horse to be cortically blind but still have dazzle reflexes, or
to have PLRs but not dazzle reflexes. For a PLR, the stimulus
pathway is via the optic nerves and optic tracts to the
midbrain and thence to the efferent parasympathetic fibers
of the oculomotor nerve. Fibers in the afferent limb of the
reflex (i.e., optic nerve, optic tracts) pass on the same side
and cross over at the optic chiasm and in the midbrain.
Results of testing of menace responses along with direct and
consensual PLRs usually allow anatomic localization of a
lesion in the PLR pathways. In brief, without consideration
of effects on consensual PLR, a lesion in an optic nerve
affects the direct PLR and the menace on the same side; a
lesion in an optic tract (rostral to the thalamus) affects the
contralateral menace but does not affect direct PLR from
either side, and a lesion in the midbrain or oculomotor
ergve affects the ipsilateral PLR but not the menace
responses.

Mydriasis is caused either by increased sympathetic dilator
tone, by interference with the afferent arm of the PLR in
the optic nerve, or by damage to the oculomotor nucleus or
nerve. Mydriasis caused by sympathetic overstimulation is
usually bilateral, and PLRs are normal. With a complete
optic nerve lesion on one side, slight ipsilateral mydriasis is
seen. Light directed into the opposite eye constricts the
mydriatic pupil. With complete oculomotor nerve lesions,
the ipsilateral pupil is fixed and dilated and unresponsive to
light directed into either pupil; however, light directed into
the fixed pupil causes reflex constriction of the pupil on the
opposite side.

Miosis occurs because of removal of sympathetic dilator
influence to the pupil or possibly because of excessive stim-
ulation of pupillary constrictors. The sympathetic pathway
can be affected anywhere along the three-neuron pathway
from the midbrain to the eye. With damage anywhere along
the preganglionic (2nd) or postganglionic (3rd) neurons
of the sympathetic supply to the head, there are signs of
Horner’s syndrome in addition to ipsilateral miosis. If the
lesion affects the 1st (upper motor) neuron, there most
likely will be widespread areas of spontaneous sweating over
one half of the head, neck, and torso, with additional signs
of brain stem or spinal cord disease such as obtundation
and ataxia and weakness of limbs. Early in the course of
cerebral swelling, there often is miosis bilaterally. This is
thought to be the result of either removal of sympathetic
influences to the eyes or facilitation by upper motor neurons
of the constrictor effects of oculomotor nerves.
**Diag nostic Procedures**

**Associated Clinical Signs**

Horses with abnormal PLR because of cerebral swelling have other signs of forebrain disease such as obtundation, dementia, and cortical blindness. Within 4 weeks of optic nerve injury, abnormal pigmentation of the fundus develops and there is atrophy of the vasculature of the optic disc. In addition to miosis and ptosis, interruption of the sympathetic supply to the head causes other signs of Horner’s syndrome, including spontaneous facial sweating and hyperemia of mucous membranes.

**Position and Movement of the Eyeballs**

**Examination**

While continuing to stand in front of the horse, observe the position and size of the pupils while the head is held level (i.e., a line through the center of each eyeball is parallel to the ground). While keeping the head level, lift the chin slowly. The eyeballs should remain stationary while the chin moves upward; thus, the eyes rotate ventrally relative to the long axis of the head. In horses with vestibular disease, abnormal eye positions are exaggerated by this maneuver.

If the pupils are in abnormal positions, try to position the head in such a way (usually by rotation) that the pupils are normally oriented relative to the transverse axis of the head. For example, a horse with vestibular disease often has ventral deviation of the eyeball on the side of the lesion and dorsal deviation on the opposite side (Fig. 50-4). Eye position can be normalized relative to the axis of the head simply by rotating the head in the direction of the ventrally deviated eye. The abnormal position of the eyes in horses with vestibular disease is termed vestibular strabismus. True strabismus is eye deviation that cannot be corrected by repositioning the head and usually reflects dysfunction of nerves to the extraocular muscles (i.e., oculomotor, trochlear, or abducens nerves). In horses with strabismus, the eyeball may be rotated medially or laterally, clockwise or counterclockwise. Newborn foals normally have slight dorsomedial rotation of the pupils compared with older horses.

Further assess abducens nerve function by performing a modified corneal reflex. Hold the eyelids closed and, through the eyelid, push the eyeball medially. The normal response to this maneuver is retraction (adduction) of the eyeball. This reflex requires intact sensory branches of the trigeminal nerve, central connections in the hindbrain, and motor fibers of the abducens nerve.

Move the horse’s head in a horizontal arc from side to side and observe the movements of the eyeballs. Signs of physiologic nystagmus should normally be elicited—namely, a series of horizontal movements of the eyeball consisting of a rapid phase in the direction of head movement followed by a slow phase in the opposite direction. Each fast phase is accompanied by an eye blink. Physiologic nystagmus is normal and should be distinguished from eye movements characteristic of vestibular disease: spontaneous nystagmus, which occurs when the head is stationary and in a neutral position, and positional nystagmus, which occurs only when the head is moved to certain positions. In horses with asymmetric vestibular disease, physiologic nystagmus is often abnormal or absent when the head is moved toward the side of the lesion.

**Lesion Location**

For horses with vestibular strabismus, the causative lesion could be anywhere in the peripheral or central vestibular system (including connections with the cerebellum and nerves to the extraocular muscles), usually on the same side as the ventrally deviated eye (described more fully under “Orientation and Coordination of the Head,” earlier). A horse exhibiting true strabismus most likely has a lesion in cranial nerve III, IV, or VI (or its roots or nuclei). These nerves exit the midbrain or hindbrain and pass a short distance to the oblique and rectus muscles of the eye.

**Associated Clinical Signs**

The roots of the nerves to the extraocular muscles are subject to dorsal pressure exerted by the cerebrum as it swells and herniates under the tentorium cerebelli. Other signs associated with cerebral swelling are obtundation, blindness, seizures, and fluctuant to dilated fixed pupils. There may also be jerky head movements as a result of pressure on the cerebellum. As compression of the midbrain and rostral hindbrain becomes more severe, obtundation progresses to coma with decerebrate posturing. With more focal lesions of the nerves or their nuclei, mydriasis (III) or defective modified corneal reflex (VI) is likely.

**Swallowing**

**Examination**

It is difficult to assess competence for swallowing during a physical examination. On the basis of history and observation, note whether feed, water, or saliva return through the nose, especially when the horse eats or drinks. Pass a nasogastric tube into the pharynx and assess effectiveness of swallowing movements as the horse attempts to move the tube into the esophagus.

---

**Figure 50-4. Vestibular strabismus in a horse with eastern equine encephalomyelitis (EEE).** This yearling Quarter Horse presented initially with high fever and a left head tilt. When the head was straightened out and the chin lifted, the left eye deviated downward and the right eye upward.
Lesion Location
Involvement of the nucleus ambiguus in the hindbrain, or the roots or peripheral parts of one or both glossopharyngeal, vagus, or spinal accessory nerves, can cause dysphagia. These nerves are particularly vulnerable to damage as they pass over the guttural pouches.

Associated Clinical Signs
There is frequently coughing, especially during eating, and signs of pneumonia secondary to aspiration of feed. With bilateral laryngeal paresis because of involvement of the vagus nerves or branches, there may be inspiratory stridor at rest. At exercise, minor or unilateral laryngeal paresis (involvement of cranial nerve X or branches) may be evident as a "roaring" sound during inspiration; involvement of cranial nerve IX, X, or XI may lead to displacement of the soft palate and expiratory stridor. The slap test, which is described later, is negative on the paralyzed side.

Tongue Examination
Pull the jaws slightly apart and observe the movements of the unrestrained tongue. With unilateral weakness, the tongue curls toward the weak side. Grasp the tongue from one side after inserting the hand through the interdental space. Note resistance of the tongue to being stretched and look for atrophy (Fig. 50-5) and muscular fasciculations. Gently pinch the side of the tongue with a hemostat and look for reflex retraction. Pull the tongue out one side of the mouth, release it, and look for retraction of the tongue back into the mouth. In normal horses, one or two chewing movements occur as the tongue is quickly retracted.

Lesion Location
Tongue deviation, muscle atrophy, and/or fasciculations reflect involvement of a hypoglossal nerve or root. Delayed or absent retraction of the tongue back into the mouth can occur with any brain disease, probably because of involvement of upper motor neurons that regulate the actions of hypoglossal nerves.

Associated Clinical Signs
With delayed retraction caused by extensive brain disease, there is usually profound obtundation, often with ataxia and weakness of the trunk and limbs. Because the hypoglossal nerve is close to cranial nerves IX, X, and XI as they pass over the guttural pouch, signs of dysphagia and respiratory paralysis may accompany tongue atrophy in horses with guttural pouch disease.

General Examination of the Neck, Trunk, and Limbs Examination
With the horse standing squarely, assess muscle mass, paying particular attention to asymmetries. Note any circumscribed or asymmetric areas of sweating. Firmly press the cranial edge of each of the cervical transverse processes from C3 to C6 on each side to test for a pain response. Put pressure on the C6-C7 intervertebral joints by pushing medial to the deep pectoral muscle in front of the shoulder on each side. Test lateral neck flexion by enticing the horse to move its head toward feed held at the point of the elbow.

Lesion Location
Neck pain revealed by palpation or reluctance to turn laterally may follow any neck trauma but usually reflects arthritis of intervertebral joints.

Severe or rapidly developing muscle atrophy indicates denervation and is a localizing sign. Neurogenic muscle atrophy is caused by damage to the lower motor neuron in the ventral column of the gray matter, nerve roots, or peripheral nerves supplying that muscle. Neurogenic atrophy of thoracic limb musculature results from lesions of the C6 to T2 spinal cord segments, brachial plexus, or peripheral nerves, whereas atrophy of pelvic limb muscles reflects involvement of L3 to S2. Anesthesia of a strip of skin is caused by loss of the segmental sensory nerve, dorsal nerve root, or connections in the spinal cord. Because sympathetic fibers are distributed with spinal nerves, spontaneous sweating may occur over denervated skin.

Associated Clinical Signs
Arthritic neck pain may be detected in wobblers, especially those older than 2 years. Neurogenic atrophy usually causes limb weakness and gait abnormality and may be associated with other signs of spinal cord disease. For example, there may be ataxia and weakness in a pelvic limb because of upper motor neuron damage at C6, and atrophy of the
triceps and weakness of the thoracic limb on the same side because of a gray matter lesion in the same segment.

**Slap Test**

**Examination**

While standing on the left side, reach under the horse's neck and hook the index and middle fingers of the left hand over the highest palpable point of the larynx—the muscular process of the arytenoid. Have the handler move the head slightly to the left of midline. Gently strike the horse behind the withers several times with the palm of the right hand. The expected response is slight palpable movement (adduction) of the arytenoid in response to each slap. Repeat the procedure from the right side. More information on this test is found in Chapter 44.

**Lesion Location**

Sensory input to this reflex is the sensory nerves and roots under the area that is slapped (approximately T7 to T11). Central pathways are thought to cross to the other side at this level, and then they pass rostrally to the nucleus ambiguus. Next, efferent fibers pass out in the vagus nerve via the recurrent laryngeal nerve to innervate the contralateral laryngeal adductor muscles. Severe cervical spinal cord disease often affects this test bilaterally, and the vagus and recurrent laryngeal nerves may be affected at the guttural pouch or within the jugular groove. Variations in neck anatomy make this reflex easy to palpate in some horses but difficult or impossible in others.

**Associated Clinical Signs**

Other signs of cervical spinal cord disease include ataxia and weakness of the trunk and limbs. Dysphagia and aspiration pneumonia are further signs of guttural pouch disease, and Horner's syndrome may also be seen when there is involvement of the vago sympathetic trunk deep to the jugular groove.

**Cervicofacial Reflex**

**Examination**

Place the left index and middle fingers at the commissure of the left lip, then strike the skin over the brachiocephalicus muscle with the closed tip of the hemostat. Begin at the cranial end of the neck and continue back to the shoulder. The expected responses are facial contraction (detected as retraction of the commissure of the lip) and contraction of the brachiocephalicus and cutaneous colli (observed as shrugging of the shoulder, lateral jerking of the head, and twitching of the skin of the neck).

**Lesion Location**

 Interruption of reflex components in the facial nerve (including the cervical sensory branch), cervical nerves or roots (sensory or motor), or local cervical spinal cord segments can affect the cervicofacial reflex. This reflex is typically reduced at the level of a cervical spinal cord lesion but is normal cranial and caudal to the lesion.

**Associated Clinical Signs**

There may be other signs of facial paralysis or cervical spinal cord disease (e.g., limb ataxia and weakness). With involvement of cervical sensory nerves or roots, there may be a strip of cutaneous anesthesia that corresponds to the area of diminished cervicofacial reflex. Asymmetric damage to the most cranial cervical nerves may lead to signs suggestive of peripheral vestibular disease.

**Cutaneus Trunci Reflex (Panniculus)**

**Examination**

When examining the reflex on the left side of the horse, use the extended right thumb to firmly prod the skin of the sensory field, beginning cranially just behind the shoulder and extending caudally to the last intercostal space. Check every intercostal space both ventrally and dorsally. For safety, firmly grasp the back of the mane with the left hand and face backward when testing the reflex, because horses that resent this test will try to kick the examiner. A normal response is twitching of the skin, with or without indication of conscious perception of the stimulus. Regardless of the site of stimulus, the twitch response is the same.

**Lesion Location**

The reflex pathway is input from sensory thoracic nerves to the ipsilateral spinal cord, where it courses rostrally via interneurons to end in the C8 and L1 segments, and thence via the brachial plexus to the lateral thoracic nerve and the cutaneous trunci muscle. Interruption of this pathway in the spinal cord white matter results in loss of the reflex from approximately the point of the lesion caudally. A lesion of the sensory nerve will affect only the reflex within the same dermatome (skin strip), whereas loss of lateral thoracic nerve function ablates the entire ipsilateral reflex.

**Associated Clinical Signs**

A strip of cutaneous anesthesia may overlay the cranial edge of the hyporeflexic zone when the spinal cord lesion affects interneurons coursing cranially and sensory connections from the segmental spinal nerve. Ataxia and weakness of the ipsilateral pelvic limb is usually found in such cases.

**Back Reflexes**

**Examination**

After making sure that the pelvic limbs are positioned equally and squarely, stroke the closed tip of the hemostat caudally along the skin over the longissimus muscle, from mid thorax caudally to the level of the tuber coxae. For safety, hold the back part of the mane with the other hand. The expected response is brisk extension of the back and pelvis followed quickly by return to normal posture. Next, stroke the hemostat caudally along the skin over the glutal muscles. This should elicit flexion, followed by relaxation of the lumbar spine and pelvis. Common abnormal reactions to these tests include (1) partial collapse in the pelvic limbs, (2) wobbling of the pelvis from side to side, and (3) no response.
Lesion Location
Abnormal results of the back tests correlate with truncal and pelvic limb weakness and ataxia caused by spinal cord disease.

Associated Clinical Signs
Expect other signs of pelvic limb weakness and ataxia such as toe-dragging and circumduction.

Tests for Limb Strength
Examination
During the passive part of the examination, it is difficult to detect mild thoracic limb weakness. Only very weak horses buckle a thoracic limb in response to downward pressure exerted over the withers. The hopping test is more sensitive. From the left side, hold the halter with the left hand. Pick up the left leg then push the head toward the right side while leaning against the left shoulder (Fig. 50-6). Normal horses use the right limb to hop briskly around a circle centered on the pelvic limbs. With limb weakness, the response may be delayed so that the horse leans markedly before hopping, or the limb may buckle after landing.

Strength of the pelvic limbs is evaluated by resistance to pressure over the pelvis and to a sideways pull on the tail. Additional insight is provided by the back reflexes described earlier. To test resistance to dorsal pressure, stand on one side of the horse and hook the fingers over the opposite tuber sacrale. Use maximal effort to try to collapse the near limb. Only weak horses buckle in response to such pressure. The tail-pull test is done both at rest and while the horse is walking in a straight line. With the horse standing squarely, take the tail and pull sideways with gradually increasing force. After initial slight movement in the direction of pull, normal horses usually cannot be moved sideways, even with strong pressure. Next, pull sideways on the tail while the horse is walking in a straight line. Always work on the same side as the handler. Exert moderate lateral pressure during all phases of the stride, and then rhythmically increase pressure as the horse supports weight on the near leg. Normal horses of 450-kg bodyweight can be moved only slightly to the side. Response to this test varies according to the size and strength of the examiner and the bodyweight and temperament of the horse. Perform the test in mirror-image fashion from the right side (i.e., with the horse being led from the right side). Interpretation of this test requires practice and experience on the part of the examiner.

Lesion Location
If a full-size adult horse can easily be pulled sideways at rest, there is probably interruption of the antigravity myotactic reflex pathway. Practically, such a lesion most likely is located either in the ventral gray matter, or in the roots (L3 to L5) that form the femoral nerve, or in the femoral nerve itself. If cutaneous sensation over the saphenous vein is absent or reduced, the lesion is central to the ventral aspect of the shaft of the ilium (the site at which the sensory saphenous vein joins the femoral nerve). The much more common finding—namely, lack of resistance to tail-pull only during walking—is consistent with an ipsilateral spinal cord lesion affecting descending upper motor neurons anywhere from C1 to T2, inclusive.

Associated Clinical Signs
Depending on the location of the lesion, there may be interference with long spinal reflexes, hypalgesia of skin strips, spontaneous sweating of skin strips, or atrophy of musculature, in addition to alterations in gait.

Gait
Examination
Have the handler walk the horse in straight lines, leading alternately from the left and the right side. The handler should be instructed to keep the horse's head and neck as straight as possible during walking. When the horse turns its head to one side, there is reciprocal and potentially confusing movement of the pelvis toward the same side. Follow directly behind the horse. From this vantage point, evaluate leg position and stride symmetry. Also, watch for excessive (1) side-to-side (wobbling) movement of the pelvis, (2) up-and-down movement of the tuber coxae (pelvic roll), and (3) side-to-side rotation of an imaginary line from the tailhead to the tuber sacrale (pelvic yaw). Next, watch the gait from the side while walking in stride with the pelvic and then thoracic limbs. Note any toe-dragging, knuckling, stride-length asymmetries, and abnormal protractive movements such as hyperflexion, stiffness (hypometria), or excessive...
range of movement (hypermetria). Often, these signs are most obvious as the horse transitions from standing still to walking. Repeat this part of the examination with the horse's chin lifted and with the horse walking up and down a modest slope. These maneuvers exacerbate most gait abnormalities, especially stiffness of the thoracic limbs.

Take the horse in hand for the next part of the examination. Hold the lead rope with the left hand and, by walking backward, lead the horse in counterclockwise circles (Fig. 50-7). It is very important that the horse be always walking forward in these circles. Vary the diameter, making the circles alternately small and large. Observe carefully the motion of the right (outside) pelvic limb by looking under the horse's torso. This limb will often arc out widely on the outside of the circle (i.e., circumduct) in horses with spinal cord disease. In mirror-image fashion, lead the horse from the right side in clockwise circles.

Next, pull the horse sideways in tight circles in either direction. This is done from a position slightly behind the shoulder by pulling the lead rope at an angle sideways and caudally (Fig. 50-8). If done correctly in normal horses, the opposite thoracic limb should cross in front of the supporting limb and the pelvic limbs should move reciprocally, causing the horse to pivot around a point midway between the thoracic and pelvic limbs. Horses that are weak and ataxic tend to sag backward in the hindquarters before they start to move, and then pivot the front part of the body around one or both pelvic limbs. There is often also interference between or otherwise inappropriate placement of thoracic limbs.

Use the lead rope to push the horse straight backward. A normal horse should move backward in two-beat fashion, with simultaneous movement of diagonally opposite pairs of limbs (e.g., left thoracic and right pelvic limbs). A horse with spinal cord disease may sag backward before moving and slide its hooves along the ground rather than picking them up and placing them.

**Lesion Location**

Signs of limb weakness and ataxia suggest spinal cord (or, rarely, peripheral nerve) damage at or cranial to the affected limb. If there is obvious ataxia and weakness in thoracic and pelvic limbs, there is likely to be at least one lesion in the spinal cord somewhere between the front of the C1 and back of the T2 spinal cord segments. When the signs are caused by external compression of the cervical spinal cord (e.g., in cervical stenotic myelopathy), signs in the pelvic limbs are usually worse than those in the thoracic limbs. When, in such cases, the pelvic limb signs are mild, thoracic limbs may appear normal. In contrast, when thoracic limbs are normal but there is moderate or severe ataxia and weakness in the pelvic limbs, there is likely to be at least one lesion caudal to T2 and cranial to S3. If one or both thoracic limbs are abnormal in a horse that has normal pelvic-limb...
gait, the gray matter of the C6 to T2 spinal cord segments (without white matter involvement), the roots or nerves of the brachial plexus, or the peripheral nerves to the limbs are probably affected. Asymmetric lesions in the spinal cord cause signs that are more severe on the side of the lesion. Occasionally, there are signs of weakness without ataxia (e.g., botulism, equine motor neuron disease) or ataxia without weakness (e.g., cerebellar atrophy, peripheral vestibular disease). Additional signs, such as defective reflexes (cervicofacial, slap, or cutaneous trunki), neurogenic muscle atrophy, or cutaneous anesthesia, often help to localize the spinal cord lesion.

Associated Clinical Signs
Abnormal responses to tests for limb strength, reduced or absent long spinal reflexes, and strips of cutaneous anesthesia or spontaneous sweating may accompany lesions of the spinal cord or peripheral nerves.

Testing of Recumbent Horses

Examination
Note whether or not the horse moves its limbs voluntarily without stimulation. If possible, assist and stimulate the horse in such a way as to assess which of the following best describes the horse’s maximal voluntary motor function: (1) lifts head off the ground; (2) rolls shoulders and chest into a sternal position, or (3) straightens thoracic limbs and assumes a “dog-sitting” position.

Check long spinal reflexes (cervicofacial, cutaneous trunk, slap) and test cutaneous sensation systematically over the limbs and torso. Test sensation at each site by grasping a fold of skin between the jaws of the hemostat and firmly squeezing the skin and watching for evidence of a conscious response by the horse. This is a behavioral reaction and must be distinguished from a reflex response. Sensory fields for some peripheral nerves of horses have been described.

Test pelvic limb reflexes and function. First, assess extensor tone in the limb by testing resistance to passive flexion. Next, perform the flexion test by pinching skin on the distal limb with a hemostat. If there is no response, try pinching skin elsewhere on the leg. A normal response is flexion of the limb, usually with some evidence that the horse can feel the skin pinch. When abnormal, the flexor response may be reduced or absent, and it may be accompanied by reflex extension of the contralateral digit (crossed extensor reflex). To test the patellar reflex, hold the pelvic limb in a moderately flexed position, and strike the skin over the middle patellar ligament (Fig. 50-9). A twitch handle works well for this purpose in full-size horses; a patellar hammer or reversed hemostat can be used in foals. The expected response is brisk extension of the stifle. If the reflex is absent, move the leg into different positions and retest. Classify the response as absent, normal, or increased. Other extension reflexes in the pelvic limb cannot be elicited reliably but should be tested for comparison with the opposite leg. These include (1) the tibial reflex—tap just behind the greater trochanter; (2) the gastrocnemius reflex—strike the Achilles tendon close to its insertion; and (3) the anterior tibial reflex—strike the middle of the anterior tibial muscle.

Test thoracic limb reflexes and function. Assess extensor tone and evaluate the flexor reflex as described for the pelvic limb. No other reflex can be obtained consistently in the thoracic limbs, but, for comparison with the opposite limb, test the following: (1) triceps reflex—with the limb in flexed position, strike the triceps muscle and watch for elbow extension; (2) biceps reflex—strike the front of the elbow and watch for extension of the shoulder and flexion of the elbow joint; and (3) strike the middle of the extensor carpi radialis muscle and look for extension of the carpus.

Lesion Location
If a horse can dog-sit, the principal spinal cord lesion is probably behind T2. Inability of a horse to roll from lateral into sternal recumbency is associated with severe lesions (usually involving gray matter) of the caudal cervical segments, whereas serious injury to the spinal cord in the rostral part of the neck may also prevent a horse from raising its head off the ground.

With involvement of lower motor neurons to limb muscles, there is reduced or absent extensor tone. Limb reflexes are reduced or abolished if the sensory nerves, motor nerves, or central components of the reflexes are affected. The afferent, central, and efferent parts of important reflexes are listed in Table 50-1. In contrast, extensor tone and limb reflexes may be exaggerated beginning several days after injury to descending upper motor neurons. For example, after trauma to the spinal cord at the T13 segment, patellar reflexes and pelvic extensor muscle tone may be exaggerated.
If there is no response to strong pinching of the skin over caudal regions of the body, there is probably catastrophic damage to the spinal cord cranial to the anesthetic area. If there is no response to deep pain for more than 24 hours, there is at least functional transection of the spinal cord.

**Associated Clinical Signs**

Large horses that remain recumbent for more than a few hours often have reduced skin sensation in the distal limbs secondary to pressure-induced injury of superficial sensory nerves. This complicates interpretation of tests for flexor reflexes and for presence of deep pain.

**Tail and Anus Examination**

Assess tail strength by lifting (extending) the tail. Prod or pinch the skin adjacent to the anus and observe the anal contraction and tail-clamp reflexes. If these reflexes are abnormal or if the history suggests possible cauda equina syndrome, perform a rectal examination to assess rectal tone and bladder size and tone. Assess muscular symmetry of the tail and test cutaneous sensation over the tail and caudal structures.

**Lesion Location**

Anesthesia and areflexia of the tail, penis, and perineum and paralysis of the anus, rectum, bladder, and penis are signs of **cauda equina syndrome**. Lesions of the spinal cord or nerve roots caudal to the S2 spinal cord segment cause some or all of the signs of cauda equina syndrome. The bundled roots forming the cauda equina are vulnerable as they pass through the sacrum and proximal coccygeal vertebrae.

**Associated Clinical Signs**

With involvement of S2 and more cranial nerve roots, expect to see signs of pelvic limb weakness in addition to cauda equina syndrome. Colic caused by obstipation may be the presenting sign of rectal paralysis, and urinary overflow incontinence is a sign of bladder paralysis.

---

**CEREBROSPINAL FLUID COLLECTION**

Atlantooccipital (AO) cerebrospinal fluid (CSF) collection under general anesthesia is simple, and iatrogenic blood contamination is seldom a problem. Lumbosacral (LS) collection has the advantage of not requiring anesthesia, but the procedure is technically more challenging than AO collection and significant blood contamination may occur. Because CSF flows caudally over the spinal cord from sites of production in the brain, LS samples can theoretically reflect changes anywhere in the CNS, whereas AO samples may not reflect caudal spinal cord disease. In general, in cases where the horse’s physical condition does not dictate the procedure used, select the collection site that is closest to the likely site of the lesion.

**Atlantooccipital Cerebrospinal Fluid Collection**

Anesthetize the horse (e.g., 1 mg/kg of xylazine and 2 mg/kg of ketamine, both given IV) and position it in lateral recumbency. This procedure should not be performed in standing horses. Clip and surgically prepare a rectangle of skin approximately 10 cm (4 inches) wide and 15 cm (6 inches) long centered on the dorsal midline and beginning just behind the forelock. Extend the prepared area on the side facing up so that a 2.5-cm (1-inch) strip is clipped over the cranial border of the wing of the atlas. In horses heavier than 150 kg bodyweight, use an 8.23-cm (3.5-inch) 18- or 20-gauge stiletted spinal needle. In foals, use a regular 3.75-cm (1.5-inch) 20-gauge needle. Flex the atlantooccipital joint in the median sagittal plane to an angle of 90 degrees or less. This is conveniently done if the collector kneels in such a way as to flex the head with the inside of the knee while leaning over the neck to place the needle. The needle is inserted at the intersection of lines running along the front of the atlas and along the dorsal midline (Fig. 50-10). Insert the needle through the skin and then pass it in the median plane by aiming at the middle of the lower jaw. The needle is passed through the funicular part of the ligamentum nuchae and advanced until there is a popping sensation as the needle penetrates the atlantooccipital membrane, the cervical dura, and arachnoid mater. In practice, the stilette is withdrawn from the needle each time there is a popping sensation.

sensation. CSF should flow freely from the hub when the subarachnoid space is entered. This can happen anywhere from 2.5 to 8.3 cm (1.0 to 3.5 inches) beneath the skin surface, depending on the size, sex, breed, and condition of the horse. Collect two or three aliquots of 1 to 5 mL of CSF, depending on need, either by aspirating drops as they fall from the hub of the needle or by attaching a syringe to the hub and aspirating directly. The last aliquot is least likely to be contaminated with blood and should be retained for analysis. Replace the stilette and withdraw the needle.

There is very little morbidity associated with this procedure; however, occasionally a horse will hold its head stiffly in an extended position for a few days afterward. This is not associated with fever (in which case infection would be likely) and may be analogous to the headache that occurs in some humans after CSF aspiration. The condition responds well to the use of a nonsteroidal anti-inflammatory drug (NSAID).

**Lumbosacral CSF Collection**

This procedure is conveniently performed in stocks so that the collector can stand on a raised platform alongside the horse; however, it also can be done in a stall with the horse pushed against a wall. In either case, it is preferable that only a nose twitch be used. If a sedative must be given, use the lowest dose that controls the horse without causing the hindquarters to sway and wobble unduly.

The key landmarks for this procedure are the tuber sacrale and the dorsal spinous process of the 2nd sacral vertebra. The paired tubera sacrale are located near the midline and can be found between the caudal margins of the tuber coxae at approximately the highest point of the rump. The dorsal (superficial) edge of each sacral tuberosity can be palpated through the skin as a slender ridge beginning adjacent to the sacral spine and progressing cranially and slightly laterally for several centimeters. When viewed from above, the paired tubera sacrale thus form a V with the vertex caudal. The correct tap site is located on the midline within or slightly in front of the V. To find the site, palpate the dorsal spinous processes of the caudal sacrum with the thumb, then slide the thumb forward until a 2- to 3-cm-long depression is located on the midline (between the spinous processes of the 2nd sacral and 6th lumbar vertebrae). Clip and surgically prepare a rectangular section of skin centered on this site (Fig. 50-11).

Infiltrate 0.5 to 1.0 mL of local anesthetic into the skin of the tap site, and make a sagittally oriented stab through the skin with a no. 15 scalpel blade. Rest both forearms on the horse’s back while holding the hub of the needle with both hands. The needle is inserted along the intersection of the median and transverse planes. It is helpful to have an assistant watch from behind the horse to guide side-to-side orientation of the needle. Advance the needle until (1) a slight “pop” is felt as the needle traverses the ligamentum flavum, (2) there is an involuntary response from the horse (usually brisk extension of the tail and pelvis), or (3) the point of the needle strikes the bottom of the vertebral canal. Remove the stilette, attach a syringe, and apply gentle aspiration pressure. To obtain flow of CSF, it may be necessary to rotate the needle or slightly retract it (or both) during attempted aspiration. Advance the needle only if the stilette is in place. CSF may flow more easily if both jugular veins are occluded (thus increasing intracranial pressure). Collect an initial sample of 2 to 5 mL (or more if the sample is visibly contaminated with blood) to “clear” iatrogenic blood contamination; then collect another sample for analysis. Reinsert the stilette and remove the needle.

Rarely, horses are sensitive to touch near the tap site for several days after the procedure. Occasional cases of cauda equina syndrome have occurred because of development of epidural abscessation at the tap site.

**CSF ANALYSIS**

At least 1 mL of CSF anticoagulated with ethylenediaminetetra-acetic acid (EDTA) should be submitted for cytologic examination. A slide for this purpose should be prepared within 2 hours of collection by low-speed centrifugation of the sample. Alternatively, cell morphology can be preserved by mixing the sample with an equal volume of 50% ethyl alcohol. Standard chemistry analyses and immunoassays can also be performed on these samples. Normal values are shown in Table 50-2. It is important to minimize blood contamination of the sample so that results do not reflect admixture of plasma and CSF. For most purposes, a red blood cell count of less than 50/µL is acceptable.

**DIAGNOSTIC IMAGING EXAMINATION**

**Survey Radiographs**

The primary reference for “Survey Radiographs” is reference 6.

**Head**

Lateral, oblique, and dorsoventral (in the standing animal) or ventrodorsal (in the anesthetized animal) views of the cranium and associated soft tissues can be obtained with portable film-screen or digital systems. On lateral radiographs, the ovoid shell of the cranial vault is seen. In foals
less than 3 months of age, the dorsal profile of the cranial cavity is interrupted by the fontanel. Other relevant structures on lateral radiographs are the petrous temporal bone, basilar bones, occipital condyles, ethmoid turbinates and ethmoid plate, frontal sinus, hyoid apparatus, guttural pouches, soft palate, and epiglottis. Oblique radiographs are useful to separate the paired stylohyoid bones and petrous temporal bones. Ventrodorsal/dorsoventral views compare these structures more directly and also show the tympanic bullae.

The parietal-occipital suture and the synchondrosis between the basisphenoid and basioccipital bones disappear by 5 years of age.

Radiographs of the head are used to diagnose frontal/parietal fractures, fractures or separation of the basilar bones, fractures of the petrous temporal bone, hemorrhage into and around the guttural pouches, soft palate displacement, stylohyoid fractures, and orbital fractures.

Cervical Spine

Radiographic examination of the cervical spine is indicated when there is deformity or palpable abnormality of the neck, ataxia or weakness of the limbs, or neck trauma, stiffness, or pain. Acceptable views of C1 to C6 are readily obtained in standing horses with the use of portable equipment, especially with fast rare-earth screens, grids, and appropriate film, newer imaging plates used for computed radiography, or direct digital systems. For normal 450-kg horses, more powerful equipment (75 to 100 kV, 75 to 100 mAs) is required. Complete radiographic assessment of the cervical spine of a full-size horse requires four to five overlapping views: occiput and C1, C1 to C3, C3 to C5, C5 to C7, and C7 to T1 (Fig. 50-12). It is very important to obtain true lateral projections, since a slight obliquity complicates interpretation of the image. In anesthetized horses, additional views including lateral-flexed, lateral-extended, and ventrodorsal (C1 to C5 or C6), can be obtained.

The horse has seven cervical vertebrae. The cervical spine of the standing horse adopts a reverse-S shape when viewed from the left, with gradual flexion at the cranial end and extension caudally. Within each vertebra is a rectangular-appearing vertebral foramen; the continuous cylinder formed by these foramina is the vertebral canal. Absolute values for minimal sagittal diameter, sagittal ratio, and corrected minimal sagittal diameter of the cervical vertebral canal have been reported. Measurement of sagittal diameter is used to detect stenosis of the vertebral canal and is described in detail in Chapter 51.

The atlas (C1) has no body or articular processes. The axis (C2) has a large dorsal spinous process and a cranially projecting dens (odontoid process). There are separate ossification centers for the dens, head, body, and cranial epiphysis of C2. The body of each of the C3 to C7 vertebrae has cranial and caudal epiphyses, and there is an extra center of ossification in the ventral processes of C6. The transverse processes of C6 differ from those of C3 to C5 by presenting an additional ventral process. This ventral process contributes to the ventral profile of C6 in lateral projections.

AO, from atlantooccipital cerebrospinal fluid; AST, aspartate transaminase; LDH, lactate dehydrogenase; LS, from lumbosacral cerebrospinal fluid; RBC, red blood cell; WBC, white blood cell.
caudal aspect of each of the bodies of C3 to C7 is smoothly concave and accommodates the convex cranial aspect of the next vertebra caudally. Intervertebral discs are radiolucent and of uniform width dorsal to ventral. The cranial and caudal articular processes of C3 to C7 form pairs of true articulations (facet joints) that are visible as smooth ovoid radiodense structures at the dorsal aspect of each intervertebral foramen. C7 is a relatively short vertebra with a small dorsal spinous process. In most horses, the dens fuses with the head of C2 at about 7 months of age, and the cranial and caudal physes of C3 to C7 close by 2 and 5 years, respectively.

Vertebral abnormalities including occipitoatlantoaxial malformation, cervical stenotic myelopathy, degenerative arthritis of the facet joints, osteomyelitis, fracture, discospondylitis, and multiple myeloma are examples of cervical spinal diseases that can be diagnosed in plain radiographs (see Chapter 51).

Thoracolumbar Spine

Thoracolumbar radiography may be performed on horses that have a history of trauma to the back, deformity of the back, acute or chronic back pain, or signs of limb weakness and ataxia that localize to this area.

Radiography of this area of the spine is difficult and requires specialized and powerful (75 to 120 kV, 100 to 250 mAs) equipment, and fast rare-earth screens and grids or computed radiograph cassettes. With this equipment, it is technically possible to obtain lateral views from T1 to L3. Caudal to L3, superimposition of the ilial wings over the lumbar vertebrae precludes useful views. Ventrodorsal images from about T9 to L6 are possible in anesthetized horses. For all areas of the thoracolumbar spine, two lateral exposures are needed for film-screen systems: one optimized for the vertebral bodies and one for the dorsal spinous process. In some cases, separate processing algorithms can be used to obtain optimized images of bodies and spinous processes from a single exposure when a computed radiography system is used.

There are 18 thoracic vertebrae and usually six lumbar vertebrae. Some horses and all donkeys have only five lumbar vertebrae. Vertebral bodies are rectangular and the vertebral canal is of uniform sagittal diameter throughout. Disc spaces are curved and of uniform thickness, whereas facet joints vary over the length of the thoracolumbar spine. Thoracic and lumbar facet joints are difficult to image on lateral radiographs. In thoracic vertebrae, ribs articulate dorsal to the disc spaces. The dorsal spinous processes of the thoracic vertebrae increase in length to T6 or T7 and become shorter in the more caudally located vertebrae. Separate ossification centers are present in the dorsal spinous processes of T2 to T8. Thoracic dorsal spinous processes slope caudally, T15 is vertical (anterior), and the dorsal spinous processes of lumbar vertebrae slope cranially. The transverse processes of lumbar vertebrae are larger than those of the thoracic vertebrae and can be identified on lateral projections. The cranial physes close by 12 months and the caudal physes by 4 years of age.

Degenerative joint disease, ossifying spondylosis, osteomyelitis, discospondylitis, and fractures and dislocations can be seen on plain films of the thoracolumbar vertebrae (see Chapter 52).

Sacrococcygeal Spine

Reasons for sacrococcygeal radiography include signs of cauda equina syndrome, and pain or deformity over the sacrum or tail. Lateral views of the sacrum may be obtained with techniques similar to those used for the lumbar
spine. The sacrum is usually poorly resolved because of overlying soft tissues, but the ventral profile can usually be seen as a straight horizontal line. The last segment of the sacrum (usually S5) is variably separated from the main body of the sacrum and may be confused with the first coccygeal vertebra. Ventrodorsal images can be obtained under anesthesia by using the pelvic technique described in Chapter 53. The sacroiliac joints can be seen on this projection.

Scout films of this area are most often useful in horses with signs of cauda equina syndrome caused by sacral or coccygeal fractures or dislocations.

**Myelography**

Myelography is the technique of introducing contrast material into the subarachnoid space to outline the spinal cord and adjacent structures. In the horse, cervical myelography is commonly used and is indicated when cervical survey films or clinical examinations have suggested the presence of a cervical spinal cord lesion.

Myelography should be performed under general inhalation anesthesia. An NSAID (preferably flunixin meglumine or ketoprofen) should be given prior to the procedure. All of the following views should be completed within 90 minutes, and preferably within 60 minutes. Begin in lateral recumbency and take plain lateral survey films. For these views, the head and neck need to be supported in horizontal position by radiolucent cushions. Perform atlantooccipital cisternal puncture with an 18-gauge 8.3-cm (3.5-inch) needle as described earlier. Connect a short extension tube to the needle and slowly withdraw 10 mL CSF per 100 kg bodyweight (i.e., 50 mL in a 500-kg horse). Retain a sample of CSF for analysis. Next, inject the same volume of contrast material (iopamidol or iohexol) into the subarachnoid space at constant rate over 5 minutes. Withdraw the needle, then elevate the head and neck at approximately 30 degrees from the horizontal and allow another 5 minutes for caudal flow of contrast material to occur. Bring the head and neck back to the horizontal position and repeat the radiographs of the cervical spine. Next, tie the horse’s head in position to exert flexion pressure focused on the middle of the neck. Radiograph C1 to C5. Retie the head so that the caudal part of the neck is hyperextended, and radiograph C5 to C7 (Fig. 50-13). If indicated, position the horse in dorsal recumbency and take ventrodorsal views. Such views are possible from C1 to the cranial half of C6.

Neutral, flexed, and extended views are examined for evidence of dynamic or static vertebral canal stenosis or extradural compression by soft tissue. Typically, flexion reveals dynamic compression in the middle and cranial part of the neck, whereas extension views are best for dynamic compression in the caudal part of the neck. Criteria for interpretation of myelograms in cases of suspected cervical stenotic myelopathy have been reported and are described in Chapter 51.

NSAID therapy should be continued for 3 to 5 days after the procedure, and the horse should be closely observed and monitored during the first week. Fever and inappetence are common during this period if NSAIDs are not given, and they occasionally occur after NSAIDs are stopped. Seizures occur occasionally, usually within 24 hours of myelography. These are usually controlled with diazepam (0.05 to 0.1 mg/kg IV) and the horse is put on preventative anti-seizure medication (e.g., phenobarbital, 5 mg/kg PO twice a day) for at least 7 days.

**Computed Tomography**

Computed tomography (CT) is a cross-sectional imaging method that provides additional diagnostic information in situations where survey radiography is unsatisfactory. This is particularly true of the skull, where multiple soft-tissue and bony structures are superimposed on each other in two-dimensional radiographic images. Even in the cranial neck, where radiography is very useful, contrast-enhanced CT had

Figure 50-13. Cervical myelographic series in a normal horse. A to C, The neck is in a neutral position. Note that the transverse processes of C6 in this horse do not have the typical ventral extension. D, Now centered caudally, the neck is in extended position. E to F, Cranial and middle views of the neck in flexed position. (Courtesy Dr. Greg Roberts, University of Florida.)
better specificity for detection of spinal cord compression that did cervical myelography.13 Compared to radiography, CT can discriminate much smaller differences in density (0.5% versus 10%). The gray matter of the brain can be distinguished from white matter, and acellular fluids can be distinguished from blood and pus.

The principles of CT have been reviewed10 (see Chapter 75). In brief, CT images are produced in slices by an x-ray beam that rotates in a circular gantry around the object. The gantry and table carrying the patient move in precise relation to each other in a series of increments or slices. Slice thickness is typically 0.4 to 1.0 cm. As in radiographs, images are rendered in gray scale. Iodinated contrast media can be administered to enhance vascular mass lesions and to better detect diseases that disrupt the blood–brain barrier. Intravenous doses for equine CT contrast enhancement have been reported.12 Data can be reconfigured to produce images in alternative planes or in three dimensions.

CT-based studies of the anatomy of the head in adult horses and foals have been reported.13,14 The skull and first images in alternative planes or in three dimensions. T1-weighted images reveal fine sectional slices in any plane. Data can be used to reconstruct protons in a strong magnetic field, and it yields cross-sectional slices in any plane. Data can be used to reconstruct images in three dimensions. T1-weighted images reveal fine anatomic detail but lack tissue contrast. T2-weighted images are grainier than T1-weighted images, but they are more useful for detection of fluid and pathologic change. Additional contrast during T1 pulse sequence can be provided by injection of gadolinium.

Reference studies for the head have been published, and cases of intracranial neoplasia, abscesses, temporohyoid osteoarthropathy, brain abscess, cholesterinic granuloma of the choroid plexus, fracture of the basisphenoid and calvaria, and guttural pouch disease.15

Magnetic Resonance Imaging
Magnetic resonance imaging (MRI) of the skull and spine is a cross-sectional imaging technique that is less widely available than CT10,15 (see Chapter 76). The strong magnets (0.5 to 1.5 tesla) required for this type of imaging preclude the use of “standing” units designed for imaging of distal limbs. Horses must be anesthetized and all metallic objects removed.

MRI provides a gray-scale map of the behavior of tissue protons in a strong magnetic field, and it yields cross-sectional slices in any plane. Data can be used to reconstruct images in three dimensions. T1-weighted images reveal fine anatomic detail but lack tissue contrast. T2-weighted images are grainier than T1-weighted images, but they are more useful for detection of fluid and pathologic change. Additional contrast during T1 pulse sequence can be provided by injection of gadolinium.

Reference studies for the head have been published, and cases of intracranial neoplasia, abscesses, temporohyoid osteoarthropathy, hydrocephalus, and cholesterinic granuloma have been diagnosed.15 MRI is generally regarded as superior to CT for soft tissue images, whereas CT is better for bone images.

ELECTRODIAGNOSTIC TECHNIQUES
Electromyography
Needle electromyography (EMG) is the diagnostic recording of the electrical activity of muscle.16 The EMG records spontaneous activity and response to needle insertion, voluntary or reflex muscle activity, and nerve stimulation. Abnormal results are consistent with muscle damage or motor denervation of at least 2 weeks’ duration.1 Use of the EMG allows objective mapping of the size and margins of involved muscle. This is discussed more fully in Chapter 87.

Electromyography requires needle electrodes, amplifier, cathode-ray oscilloscope, and speaker. Concentric and monopolar electrodes combine reference, ground, and exploring electrodes in different combinations. The examination can be performed standing, with or without sedation, or under general anesthesia. After the needle is pushed into muscle, insertion activity, motor unit action potentials (MUAPs) during muscle contraction, and abnormal spontaneous activity are measured. Normal and abnormal responses have been described for horses. Abnormal responses include fibrillations, fasciculation potentials, positive sharp waves, complex repetitive discharges, and myotonic discharges. Each of these has characteristic electrical profiles and sounds. Reference values for amplitude and duration of normal MUAPs in conscious horses have been published.17,18 Values for horses with myopathies differed markedly from these normal values, and it is expected that values in denervated muscle would also be abnormal.

Nerve conduction studies combine nerve stimulation with EMG recording to evaluate conduction speeds in large motor nerves. These studies are performed under general anesthesia. Techniques have been described for the radial and median nerves in horses, and tibial nerve testing has been performed in horses with stringhalt.

Electroencephalography
Electrical activity arising from the cerebral cortex is recorded by subcutaneous electrodes inserted over the frontal/parietal area and displayed graphically on paper or captured for computerized analysis. Electroencephalography (EEG) is a useful tool for determining the presence, location, and extent of cerebral disease. Because of the expanded use of CT and MRI for evaluation of brain disease, the EEG is now used less frequently than it was 20 years ago.

Evoked Response Testing
The integrity of various parts of the central and peripheral nervous systems can be tested by providing a stimulus at one site and recording the electrical activity at another site. Techniques that have been used in horses include magnetic motor-evoked potentials, brain-stem auditory-evoked responses, and cortical somatosensory-evoked potentials.19-21

REFERENCES
of sclerotomal cells collect segmentally at the embryonic midline, surrounding the neural tube and the notochord, and these cells begin to separate into a cranial portion and a caudal portion. Failure of segmentation produces a block vertebra. The cranial portion of each sclerotome recombines with the caudal portion of the directly superior sclerotome in a resegmentation process known as metameric shift. Failure of recombination produces hemivertebrae. After the metameric shift, spinal nerves, which originally left the neural tube to go to the center of the sclerotome, are able to pass between the precartilaginous vertebral bodies to innervate the segmentation myotomes.

The atlas and axis form by a mechanism that is different from that of the other vertebral bodies. Part of the first cervical sclerotome plus the cranial portion of the second cervical sclerotome contribute cells to form the odontoid process and the arch of the atlas. In the cervical region, eight cervical somites generate seven cervical vertebrae because the cranial portion of the first cervical sclerotome contributes to the formation of the occiput, and the caudal portion of the eighth cervical sclerotome contributes to T1. This is the process by which eight cervical spinal nerves become associated with seven cervical vertebrae. Because the occiput, atlas, and axis are formed from shared sclerotomes, developmental abnormalities of these structures occur concomitantly, as in occipitoatlantoaxial malformation of Arabian foals. The first cervical spinal nerve passes between the base of the skull and the first cervical vertebra. The eighth cervical nerve exits below the seventh cervical vertebra and above the first thoracic vertebra. The reminder of the nerve roots exit below their corresponding vertebral bodies.

As the sclerotomes undergo shift to form the vertebral bodies, the adjacent visceral organs are differentiating, so that a noxious influence affecting development of a particular vertebral segment may affect adjacent organs at

### Normal Vertebral Development

The critical phase of vertebral development is during gastrulation (the formation of the three primary germ layers: ectoderm, mesoderm, and endoderm) and neurulation (the formation of the notochord, neural crest, and the precursors of the nervous system). The spine has its embryologic origins in the cell that is induced to migrate out of the somite, toward the notochord and the neural tube. A mass...

Cervical stenotic myelopathy (CSM) and occipitoatlantoaxial malformation (OAAM) are among the most notable abnormalities of the vertebral column of the horse. Other congenital vertebral anomalies, such as hemivertebrae, block vertebrae, and spina bifida, occur rarely in horses, with individual reports involving a small number of foals. The pathogenesis of vertebral malformations is largely unknown, but it is suspected to be multifactorial, including heredity, dietary imbalance, and in utero insult (trauma and toxin). After a brief description of normal vertebral development, the clinical presentation and pathogenesis of vertebral malformations and anomalies are described.

NORMAL VERTEBRAL DEVELOPMENT
The critical phase of vertebral development is during gastrulation (the formation of the three primary germ layers: ectoderm, mesoderm, and endoderm) and neurulation (the formation of the notochord, neural crest, and the precursors of the nervous system). The spine has its embryologic origins in the cell that is induced to migrate out of the somite, toward the notochord and the neural tube. A mass of sclerotomal cells collect segmentally at the embryonic midline, surrounding the neural tube and the notochord, and these cells begin to separate into a cranial portion and a caudal portion. Failure of segmentation produces a block vertebra. The cranial portion of each sclerotome recombines with the caudal portion of the directly superior sclerotome in a resegmentation process known as metameric shift. Failure of recombination produces hemivertebrae. After the metameric shift, spinal nerves, which originally left the neural tube to go to the center of the sclerotome, are able to pass between the precartilaginous vertebral bodies to innervate the segmentation myotomes.

The atlas and axis form by a mechanism that is different from that of the other vertebral bodies. Part of the first cervical sclerotome plus the cranial portion of the second cervical sclerotome contribute cells to form the odontoid process and the arch of the atlas. In the cervical region, eight cervical somites generate seven cervical vertebrae because the cranial portion of the first cervical sclerotome contributes to the formation of the occiput, and the caudal portion of the eighth cervical sclerotome contributes to T1. This is the process by which eight cervical spinal nerves become associated with seven cervical vertebrae. Because the occiput, atlas, and axis are formed from shared sclerotomes, developmental abnormalities of these structures occur concomitantly, as in occipitoatlantoaxial malformation of Arabian foals. The first cervical spinal nerve passes between the base of the skull and the first cervical vertebra. The eighth cervical nerve exits below the seventh cervical vertebra and above the first thoracic vertebra. The reminder of the nerve roots exit below their corresponding vertebral bodies.

As the sclerotomes undergo shift to form the vertebral bodies, the adjacent visceral organs are differentiating, so that a noxious influence affecting development of a particular vertebral segment may affect adjacent organs at
the same time. Hence, cardiac anomalies may occur with congenital malformation of the thoracic spine, and renal anomalies may be associated with congenital malformation of the lumbar spine. During axial embryogenesis, interdependence exists between the spinal cord and the axial skeleton. If this balance is distorted by genetic, traumatic, toxic, or nutritional factors, a malformation may occur. The type of malformation depends on the stage of development of the nervous system at the time of insult. Vertebral anomalies can be divided into three categories from the standpoint of basic developmental pathogenesis: malformation, disruption, and deformation.

Malformation results from a failure of embryologic differentiation of a specific anatomic structure, causing it to be absent or improperly formed during the embryonic stage of gestation. Hemivertebrae, butterfly vertebrae, and block vertebrae are examples of malformation abnormalities. Once the malformed vertebra is anatomically established, the defect may continue to adversely affect spinal development throughout the subsequent fetal and postnatal periods. The eventual type of malformation and its severity depend on the stage of the developmental or maturation cycle that is specifically affected.

Disruption is a structural defect resulting from destruction of an anatomic part during the fetal stage of gestation that formed normally during the embryonic period. This mechanism involves distal structures (e.g., flexural limb deformity or wry nose) more frequently than the axial skeleton.

Deformation is defined as alteration in the shape or structure of an individual vertebra or vertebral segment that had initially differentiated normally, during the fetal and/or postnatal periods (e.g., cervical stenotic myelopathy). Deformation abnormalities are not considered true congenital abnormalities.

CERVICAL STENOTIC MYELOPATHY

Etiology

Cervical stenotic myelopathy (CSM) (cervical vertebral malformation, wobbler syndrome) is a common cause of spinal ataxia in young horses. This developmental disorder is characterized by postnatal deformation of the cervical vertebrae, resulting in vertebral deformation, stenosis of the vertebral canal, and spinal cord compression. The etiology of CSM appears to be multifactorial, and genetic predisposition and nutrition appear to play the most significant roles in the development of the disease. Cervical stenotic myelopathy has been reported in most light and draft horse breeds, however, Thoroughbreds appear particularly predisposed. Male horses are more frequently affected than females by a ratio of 3:1. The age of onset is typically 6 months to 3 years, although mature horses (4 to 20 years) are identified with acute-onset of spinal cord compression because of cervical stenosis and arthropathy. Affected horses often demonstrate rapid growth and are more likely to have developmental orthopedic disease of the appendicular skeleton than peers.

Vertebral deformation associated with spinal cord compression includes flaring of the caudal epiphyses of the vertebral bodies, abnormal ossification of the articular facets, malalignment between adjacent vertebrae, osteoarthrits of the articular facets, and extension of the dorsal laminae. In addition to these bony deformations, the vertebral canal is narrowed from C3 through C6, regardless of the specific site of spinal cord compression. Spinal cord compression nearly always occurs in a dorsoventral plane, although lateral compression of the spinal cord has been demonstrated via computed tomography. Caudal epiphyseal flare occurs secondary to abnormal biomechanical forces on the vertebral growth plate because of subluxation and malalignment between adjacent vertebrae. Vertebral subluxation produces dynamic compression of the spinal cord during ventroflexion and is most commonly observed at C3-4, C4-5, and C5-6. Extension of the dorsal laminae contributes to spinal cord compression, because it ventrally displaces the roof of the vertebrae to produce a funnel shape, or “coning,” of the vertebral canal. Abnormal ossification of the articular facets often results from osteochondrosis of the joint surface, which quickly progresses to osteoarthritis. Degenerative arthropathy of the articular processes occurs most frequently from C5 through C7 and is associated with spinal cord compression with the neck in the neutral (static) or hyperextended position.

Histopathologic evaluation of the spinal cord reveals necrosis of the white matter, with focal loss of neurons. Neuronal fiber (Wallerian) degeneration is observed in ascending tracts cranial to the site of compression and descending tracts caudal to the site of compression.

Clinical Signs

The clinical signs of CSM result from focal compression of the cervical spinal cord between C1 and C7. Compression may occur at a single vertebral site or at more than one site in the same horse. Horses with CSM demonstrate upper motor neuron deficits to all four limbs, characterized by symmetric weakness, ataxia, and spasticity. At rest, affected horses may have a base-wide stance and demonstrate delayed responses to proprioceptive positioning. At a walk, weakness is manifested by stumbling and toe dragging; horses with prolonged clinical signs of CSM may have hooves or shoes that are chipped, worn, or squared at the toe. Ataxia (proprioceptive loss) appears as truncal sway at a walk and is manifested by circumduction and posting (pivoting on the inside limb) of the hind limbs during circling. Moderate to severely affected horses have lacerations on the heel bulbs (“wobbler heels”) and medial aspect of their forelimbs from overreaching and interference. Spasticity, characterized by a stiff-legged gait and decreased joint flexion, is often observed in moderately affected horses. Clinical signs can be exaggerated during the neurologic examination by manipulation such as tight circling, walking on a slope, or walking with the animal’s head elevated. When prompted to back, horses may stand base-wide, lean backward, and drag their forelimbs. In most instances, the rear limbs are more severely affected than the forelimbs; neuronal tracts to the rear limbs are more superficial and thus susceptible to external compression. Occasionally, forelimb ataxia may be more severe in horses with stenosis of the caudal cervical vertebrae (C6 through C7) because of compression of the cervical intumescence.

Asymmetric ataxia may be observed in horses with dorsolateral compression of the spinal cord by proliferative, degenerative articular processes; periarticular soft tissue
cord compression. Rarely, clinical signs of peripheral nerve compression are seen, such as cervical pain, atrophy of the cervical musculature, cutaneous hypalgesia, and hyporeflexia of cervical reflexes adjacent to the site of spinal cord compression. These signs are more commonly observed in horses over 4 years of age with moderate to severe arthropathy of the caudal cervical vertebrae (C5 through C7), and result from peripheral nerve compression by proliferative articular processes as the nerve root exits the vertebral canal through the intervertebral foramen. In some instances, arthropathy of the caudal cervical vertebrae may produce cervical pain and forelimb lameness as a result of peripheral nerve compression, without producing clinical signs of spinal cord compression. Affected horses typically travel with a short cranial phase of the stride and a low foot arc of one or both forelimbs, and they may stand or travel with their head and neck extended.

**Diagnosis**

The diagnosis of CSM requires collection of an accurate history, thorough physical and neurologic examinations, and radiographic evaluation of the cervical vertebrae. The clinical signs of spinal cord compression often progress for a brief period and then stabilize. Owners often report a traumatic incident with the onset of clinical signs of CSM. The traumatic incident may be the result of mild neurologic deficits, with the injury exacerbating the clinical signs of spinal cord compression. The following neurologic disorders should be considered differential diagnoses for cervical stenotic myelopathy: equine protozoal myeloencephalitis (EPM), equine degenerative myeloencephalopathy (EDM), equine herpesvirus myelitis, occipitoatlantoaxial malformation, spinal cord trauma, vertebral fracture, and vertebral abscess. Cerebrospinal fluid analysis may be performed during the diagnostic process, and it is usually unremarkable in horses with CSM. In CSM-affected horses with acute compression, mild xanthochromia or increases in protein concentration may be observed.

Assessment of plain film radiographs of the cervical vertebrae can determine the likelihood of CSM in horses with spinal ataxia. Cervical radiographs should be evaluated for subjective assessment of vertebral deformation and objective determination of vertebral canal diameter. The five characteristic deformations of the cervical vertebrae in horses with CSM include flare of the caudal epiphysis of the vertebral body, abnormal ossification of the articular processes, subluxation between adjacent vertebrae, extension of the dorsal laminae, and osteoarthritis of the articular processes (Figs. 51-1 and 51-2). Osteoarthritis of the caudal cervical vertebrae is the most frequent and severe deformation observed in CSM-affected horses. Nonetheless, degenerative arthropathy occurs in 10% to 50% of non-ataxic horses, and it is the most frequent and severe vertebral deformation in horses without CSM. Therefore, subjective evaluation of osteoarthritis of the articular processes leads to a false-positive diagnosis of CSM. Although the presence of characteristic deformations supports the diagnosis of cervical stenotic myelopathy, subjective evaluation of cervical radiographs does not reliably discriminate between CSM-affected and unaffected horses. Objective assessment of the vertebral canal diameter is more accurate than subjective evaluation of vertebral deformation for identification of CSM-affected horses.

The sagittal ratio technique has been developed to objectively determine the vertebral canal diameter in horses. The sensitivity and specificity of the sagittal ratio for identification of CSM-affected horses is approximately 89% for vertebral sites C4 through C7. The accuracy of the sagittal ratio technique for identification of CSM-affected horses, without consideration of other bony malformations of the cervical vertebrae, suggests that generalized stenosis of the vertebral canal may be the most important factor in the development of CSM. The sagittal ratio is calculated by dividing the minimal sagittal diameter of the vertebral canal by the width of the vertebral body. The minimal sagittal...
diameter of the vertebral canal is obtained by determining the narrowest diameter measured from the dorsal aspect of the vertebral body to the ventral border of the dorsal laminae (see Fig. 51-2). The vertebral body width is measured perpendicular to the vertebral canal at the widest point of the cranial aspect of the vertebral body. Because the vertebral body is located within the same anatomic plane as the vertebral canal, determination of this proportion negates the effects of magnification that result from variability in object-to-film distance. The sagittal ratio should exceed 52% from C4 through C6, and 56% at C7 in horses greater than 320 kg. The clinician should interpret radiographic examination of the cervical vertebrae to classify the patient into one of the following categories:

1. Low sagittal ratio (less than 48% at C4 through C6), moderate to severe bony deformation. Perform myelographic examination to identify sites of spinal cord compression and classify lesions as static or dynamic.
2. Marginal sagittal ratio (48% through 56%), mild to moderate bony deformation. Perform myelographic examination to confirm or exclude CSM.
3. High sagittal ratio (greater than 56%), minimal bony deformation. Pursue alternative differential diagnoses.

The semiquantitative scoring system developed by Mayhew should be used in foals less than 1 year of age to assess cervical radiographs for diagnosis of CSM. The scoring system combines the objective measurement of vertebral canal diameter and subjective evaluation of vertebral deformation. Stenosis of the vertebral canal is assessed by determination of the intervertebral and intravertebral minimal sagittal diameter (MSD). These values are corrected for radiographic magnification by dividing them by the length of the vertebral body. The maximal score for cervical vertebral stenosis is 10 points. Cervical vertebral deformation is determined by subjective assessment of five categories: encroachment of the caudal epiphysis of the vertebral body dorsally into the vertebral canal, caudal extension of the dorsal lamina to the cranial physis of the adjacent vertebra, angulation between adjacent vertebral bodies, abnormal ossification of the physeal, and osteoarthritis of the articular processes. The maximal score allotted for each category of bony deformation is 5 points. A total score of 12 or higher (maximal total score, 35) confirms the radiographic diagnosis of CSM. Stenosis of the vertebral canal and malalignment between adjacent vertebrae are the most discriminating parameters in this scoring system to differentiate CSM-affected from normal foals.

Accurate assessment of cervical radiographs requires a precise lateral radiograph of the cervical vertebrae. Obliquity of the cervical vertebrae results in indistinct margins of the ventral aspect of the vertebral canal, producing erroneous values for MSD and vertebral body width. It is difficult to obtain precise lateral radiographs of the cervical vertebrae in recumbent horses. Plain film radiographs should be obtained in the standing sedated horse whenever possible.

Although plain film radiography can determine the likelihood of CSM, it cannot replace myelographic examination for definitive diagnosis, identification of the location, number of affected sites, and classification of spinal cord compressive lesions in horses with CSM. Spinal cord compression has been defined myelographically in three ways: (1) as a 50% or greater decrease in the sagittal diameter of the dorsal and ventral contrast columns as the diagnostic criterion for CSM. Most clinicians agree that the criterion of a less-than-2-mm dorsal contrast column is too rigid, resulting in a high number of false-negative diagnoses.

In addition to providing the definitive diagnosis of CSM, myelographic examination can differentiate between dynamic (type I) and static (type II) spinal cord compression. Horses with dynamic spinal cord compression (type I) demonstrate narrowing of the dorsal and ventral contrast columns during ventroflexion of the neck, whereas spinal cord compression is not apparent with the neck in the neutral position (Fig. 51-3). Dynamic spinal cord compression usually occurs in younger horses (less than 2 years old) and is associated with instability of the cervical vertebrae, particularly from C3 through C6. Dorsal laminar extension, caudal epiphysis flare, and abnormal ossification patterns often occur in horses with dynamic spinal cord compression. Static vertebral canal stenosis (type II) is characterized by constant spinal cord compression, regardless of cervical position (Fig. 51-4). Static compression usually occurs in slightly older horses (2 to 4 years) and results from osteoarthrosis of the articular processes and proliferation of periarticular soft tissue structures. In some cases of caudal cervical arthropathy, flexion of the neck stretches the ligamentum flavum and relieves spinal cord compression, whereas extension exacerbates compression.

A complete myelographic study should include neutral and stressed (flexed and extended) views of the cervical

Figure 51-3. Myelographic examination of C2 through C4 of a 2-year-old Quarter Horse filly with dynamic spinal cord compression between the C3 and C5 articulations. The dorsal and ventral contrast columns are obliterated with the neck in the ventroflexed position. Spinal cord compression was not apparent with the neck in the neutral position (not shown).
vertebrae.\textsuperscript{19} In horses with obvious sites of spinal cord compression on neutral myelographic views, excessive flexion and extension of the neck should be avoided while obtaining dynamic views to prevent exacerbation of spinal cord injury. Horses should be monitored for 24 hours after the myelographic procedure for depression, fever, seizure, and worsening in neurologic status. Worsening of the neurologic status after myelography may result from spinal cord trauma during hyperflexion, iatrogenic puncture of the spinal cord, or chemical meningitis. Administration of phenylbutazone (4.4 mg/kg PO every 24 hours) 1 day prior to and through 1 day after the myelographic examination will attenuate fever and depression associated with chemical meningitis.

**Medical Management**

Administration of glucocorticoids, dimethyl sulfoxide, and nonsteroidal anti-inflammatory drugs may reduce edema and provide transient improvement in neurologic signs. Spontaneous recovery from CSM without dietary management or surgical intervention is not reported.\textsuperscript{22}

Horses with cervical pain and forelimb lameness as the result of cervical vertebral arthropathy may benefit from intra-articular administration of corticosteroids or chondroprotective agents, or both.\textsuperscript{23} Arthrocentesis of the cervical vertebral articulations (facets) is performed with ultrasonographic guidance using a 15-cm (6-inch), 18-gauge spinal needle in the standing sedated or recumbent horse. The cranial facet of the caudal vertebrae appears superficial to the caudal facet of the cranial vertebrae. The articular space is accessed at the cranioventral opening of the articular facet, which is angled approximately 60 degrees from the ultrasound beam. The needle should be introduced 5 cm cranial to the facet and inserted at a 30-degree angle relative to the skin surface. Joint penetration should be confirmed by aspiration of synovial fluid. If the neck is extended, the transverse process of the cranial vertebrae may obscure the path to the articulation. Intra-articular triamcinolone (6 mg per joint) or methylprednisolone (100 mg per joint) has produced a positive clinical response in more than 50% of horses with arthrosis of the articular processes. The goal of intra-articular anti-inflammatory therapy should be to decrease cervical pain or eliminate forelimb lameness. It is unlikely that intra-articular therapy will significantly improve clinical signs of spinal ataxia.

**Surgical Management**

Surgical treatment of CSM is discussed in detail in Chapter 52.

**OCCIPITOATLANTOAXIAL MALFORMATION**

Occipitioatlantoaxial malformation occurs most frequently in Arabian foals, although it has been reported in Morgans, Appaloosas, and Thoroughbreds.\textsuperscript{24-26} In Arabsians, it is inherited in an autosomal recessive manner with no sex predilection.\textsuperscript{24,25} In other breeds, a nongenetic congenital defect occurs at random during development of the vertebral column.\textsuperscript{26}

In OAAM, the developmental error occurs during embryogenesis, before the end of the 6th week of gestation.\textsuperscript{24-26} The atlas of affected foals is characterized by a small vertebral body, vertebral arches, and peglike transverse processes. The atlas is often fused to the occipital bone, resulting in spondylosis or a barely detectable atlantooccipital joint (occipitalization of the atlas). The odontoid process of the axis (dens) is malformed and hypoplastic. In some cases, the axis may be luxated ventral to the atlas, leading to fracture of the dens. The fusion between the atlas and the occipital bones may be asymmetric, leading to the development of scoliosis (Fig. 51-5).

**Clinical Signs and Diagnosis**

OAAM may be obvious at birth or detected within the first few weeks of life. Affected animals demonstrate marked
weakness and ataxia when walking and may have an extended head and neck. A clicking sound may be elicited by manipulation of the head, resulting from the dens slipping under the body of the atlas. Clinical signs worsen over time as a result of repetitive or persistent compression of the spinal cord. The malformed vertebrae lead to the formation of excess fibrous tissue within the atlantoaxial joint and adjacent ligaments, which in turn creates additional compression of the spinal cord.

Pathologic changes of the nervous system associated with OAAM include a dorsoventral flattening of the medulla oblongata and cranial cervical spinal cord. Histopathologic evaluation of affected neuronal tissue reveals gliosis, astrofibrosis, neuronal fiber degeneration, and perivascular fibrosis.

Figure 51-5. Atlantooccipital malformation in an Arabian foal. Note the atlantooccipital fusion, occipitalization of the atlas, and a hypoplastic dens.

Clinical Signs and Diagnosis
The clinical signs of AAS include weakness, spasticity, and ataxia in all four limbs, consistent with focal compressive lesions of the cervical spinal cord. Progression of signs is quite variable and depends on the degree of laxity between the axis and atlas. Clinical signs may be slowly progressive over weeks to months or may begin acutely, making spinal cord trauma an important differential diagnosis. Severe compression may produce tetraplegia.

The diagnosis may be confirmed by evaluating clinical signs, manipulating and palpating the head and neck, and taking lateral radiographs of the skull and proximal cervical region. A lateral radiograph should be obtained with the horse standing, with little manipulation of the head and neck. Widening of the space between the dorsal portion of the atlas and the axis, and a rounded cranial end of the axis are indicative of an abnormally shaped or absent dens. A myelogram is normally not required.

The prognosis for AAS is poor. Surgical stabilization of the atlantoaxial joint may be attempted as a salvage procedure. Subtotal dorsal laminectomy of the impinging dorsal arch of the atlas has been described in foals with a developmentally malformed dens. In addition, a ventral approach for stabilization of AAS resulting from a Salter-Harris type II fracture of the odontoid process has been described (see Chapter 53). Medical therapy (glucocorticoids and hyperosmotic agents) should be administered prior to surgical correction to reduce spinal cord swelling and edema. Affected foals should be maintained in a quiet environment with minimal handling to avoid additional trauma to the spinal cord.

ATLANTOAXIAL INSTABILITY
Atlantoaxial instability produces clinical signs in older foals and young horses. Subluxation of the atlas relative to the axis occurs during extension of the head and neck because of malalignment of the atlas, resulting in caudal ventral tilting of the atlas relative to the vertebral canal. The subluxation results from ligamentous laxity and malarticulation. A congenital anomaly has been suggested, although trauma may be an important pathophysiologic factor. This syndrome emphasizes the importance of evaluating this area when examining a young horse with clinical signs of spinal ataxia localized to the cervical region. Treatment is not recommended.

Differential diagnoses for OAAM, AAS, and atlantoaxial instability include cervical trauma, vertebral osteomyelitis after neonatal septicemia, cervical vertebral stenotic myelopathy, and syringomyelia, a congenital malformation of the spinal cord.

HEMIVERTEBRE
Hemivertebrae are wedge-shaped vertebral bodies in which the vertebral body apex may point dorsally, ventrally, or medially, resulting in kyphosis, lordosis, or scoliosis. Moderate to severe angulation of the spine may result in animals with hemivertebrae, and the severity of the malalignment typically worsens during growth as a result of compression by adjacent vertebrae. Hemivertebrae can result from a hemimetameric shift of somites during recombina-
nation of sclerotomes to form primordial vertebrae, or from a defect of the vascular supply at this developmental stage that results in a failure of half of the vertebral body to ossify. If metameric shift is abnormal, one right and one left hemivertebra will be adjacent to each other. The vertebrae resulting from an alteration in vascular supply may appear as unilateral, dorsal, or ventral hemivertebrae.

In horses, hemivertebrae have been observed at C5, although in most species T7 and T9 are most commonly affected. Clinical signs of hemivertebrae in foals are observed before 1 year of age. Foals demonstrate progressive vertebral malalignment, leading to kyphosis or scoliosis, with or without neurologic gait deficits. Hemivertebrae are often weaker than normal vertebrae; a sudden jump or fall may result in acute worsening of clinical signs.

THORACIC VERTEBRAL MALFORMATION
Malformation and compression of the thoracic vertebrae has been described in two unrelated horses. Both horses appeared normal for the first year of life, with ages of onset being 13 and 28 months. Clinical signs included acute-onset pelvic limb weakness and ataxia in one horse, and severe spinal cord dysfunction and paralysis of the pelvic limbs in the other. Both horses demonstrated Schiff-Sherrington phenomena, characterized by hypertonicity of the thoracic limbs associated with focal thoracic spinal cord compression. This clinical sign has been described in humans and other animals with fracture of the thoracic vertebrae, although it is a rare finding in horses. The malformation of the thoracic vertebrae was similar to malalignment and subluxation observed in horses with cervical stenotic myelopathy.

BLOCK VERTEBRAE
Block vertebrae are examples of improper somite segmentation and appear to be a result of incomplete separation of the vertebral bodies or arches, or both. The length of a block vertebra is equivalent to the number of vertebral segments involved. Block vertebrae are generally stable and do not often result in clinical signs, although the rigid fixation may result in abnormal biomechanical forces on adjacent vertebrae. The sacrum is an example of a normal block vertebra. The most commonly reported location of block vertebrae in humans and animals is C2-3 (Fig. 51-6).

BUTTERFLY VERTEBRAE
Butterfly vertebra is a rare anomaly of the equine vertebral column. The embryonic notochord is normally obliterated with the development of the vertebral bodies and remains only as the vestige of the intervertebral disc. If the notochord persists, a dorsal-to-ventral cleft results, which results in a vertebra that resembles a butterfly on a dorsoventral radiograph. Butterfly vertebrae typically do not cause spinal cord compression and do not require treatment.

VERTEBRAL DEFECTS
Spina bifida results from incomplete fusion of the dorsal components of the vertebrae during the neurulation process. It is often associated with a protrusion of the meninges (meningomyelocele) through the vertebral defect. Spina bifida (C5 through C6) with an accompanying meningomyelocele has been identified in a miniature horse foal that was unable to stand at birth. The meningomyelocele appeared as a 5-cm, fluctuant mass of the dorsal aspect of the caudal cervical region. The colt also had hydrocephalus, which is present in the vast majority of children with meningomyelocele as part of the Arnold-Chiari malformation (protrusion of caudal cerebellar tissue through the foramen magnum with concomitant caudal displacement and elongation of the medulla oblongata, pons, and fourth ventricle).

Severe posterior ataxia as the result of a congenital cleft in the ventral aspect of a vertebral body (T5) has been described in an Arabian foal. The foal had malformation and fusion of several thoracic vertebrae, with an intraspinal and extraspinal (intrathoracic) cyst. Therefore, a history of posterior paresis and ataxia present at birth should signal a need to perform a careful examination to search for malformation of the vertebral column in the thoracic region.
REFERENCES

Successful surgical treatments of developmental diseases of the spinal column depend on the most fundamental axiom of medicine: an early, complete, and accurate diagnosis. The etiology and diagnostic techniques have been discussed in Chapters 50 and 51. It is important to emphasize that successful treatment of localized cervical spinal cord compression depends on obtaining myelographic confirmation at the earliest possible time. There are many examples of horses that had had cord compression for 6 months to 1 year and improved dramatically with surgery.1-4 However, the most gratifying experiences have been when patients were treated surgically within the first 2 to 3 weeks after the recognition of clinical signs. It would be incomplete not to perform cervical myelograms on an animal with neurologic signs attributable to pathology in the cervical cord, even with an obvious subluxation of C2-3 or C3-4 on scout films. It has been the author’s (BDG) experience that the routine use of myelography may disclose multiple levels of compression, which play an important role in determining the feasibility of a surgical intervention, prognosis, and eventual outcome. Additionally, horses with clinical signs attributable to spinal cord compression with osteochondritic articular facets at C6-7 on survey radiographs may not suffer from cord compression, but rather may show signs of CNS disease caused by some other condition (e.g., protozoal myelitis).

After a thorough neurologic examination, survey radiographs and measurement of the vertebral-body-to-canal ratio, as well as location of any kyphosis, help to determine further procedures (Fig. 52-1). The authors found that in a majority of cases, when the ratio of the vertebral body width to vertebral canal width was found to be less than 0.5, the likelihood of cervical cord compression at this site is increased (Fig. 52-2). Although this is just a rough estimate, myelographic examinations can show the cervical cord compression at all sites reliably (Fig. 52-3).

CASE SELECTION FOR SURGERY
Once cervical cord compression is confirmed, other factors important to the successful outcome of the case are (1) number of sites of cord compression, (2) whether the cord compression is seen only in a flexed or extended position (i.e., is dynamic or static), (3) severity of the clinical signs, and (4) duration of clinical signs. The duration of the clinical signs may be shorter than the duration of compression, because the onset of clinical signs is not likely to
be immediate. The temperament, age, and intended use of
the animal also are important factors to consider when
discussing surgical alternatives with the owner.

According to recent investigations, only severe myelo-
graphic cord compression also causes histopathologi-
ically recognizable lesions to the spinal cord.5 Horses with mild to
moderate compression have a more favorable prognosis for
future use than horses with severe compression sites. Only
50% of severely affected horses could be ridden after surgery,
whereas 68% with initially moderate compression and as
many as 100% with mild myelographic compression were
used in various riding disciplines after their surgery.6

In the ideal situation, an adolescent animal with a grade
1 to 2 ataxia (see Chapter 50) of less than 2 weeks’ duration
is presented with a single compressive lesion at C3-4, and
the cord compression is seen only in a flexed position. The
next most desirable case would be a horse with less than
grade 2 ataxia, with only a moderate amount of cord com-
pression at C5-6 or C6-7. On the other hand, some affected
patients, despite having clinical signs of grade 3 or higher,
multiple lesions, and duration of clinical signs extending
from 3 weeks to 1 year, have raced and been successful sires
or even performance horses after being surgically treated.7
These, however, are the exception to the rule.

The temperament of the patient is important, because
there are personality changes associated with cord compres-
sion (probably related to the anxiety of being ataxic): animals may become intractable and sometimes self-
destructive. Young animals that have had little handling
(e.g., have never had their feet picked up and trimmed)
before the onset of clinical signs are at great risk for tra-
matic complications resulting from the restraint needed
during diagnostic testing, anesthetic induction, recovery,
and postoperative treatment. It is worth serious consider-
ation to delay surgery for 4 or 5 days to work with an
unbroken, adolescent horse to allow it to become confident
with human assistance and restraint before surgery.

Surgery should not be performed on a patient heavily
infested with parasites or suffering from pneumonia. Such
conditions are aggravated by the stress of transportation and
anesthesia, the latter being necessary for myelography and
surgery. Therefore, a very thorough accurate physical exami-
nation, including necessary blood work, is essential prior to
any diagnostic testing (e.g., myelography). Any economic
or time benefits realized from performing surgery close to
the time of myelography are hardly justified when the result
is postoperative pleuropneumonia. Additionally, the loca-
tion of the surgical incision makes it difficult to obtain a
transtracheal wash sample for proper antimicrobial therapy
and can sometimes compromise the healing of the initial
incision.

Because of the association of osteochondrosis with the
pathogenesis of developmental cervical cord compression, it
is important to ensure that the other commonly involved
articulations (e.g., the stifle, tarsus, fetlock, shoulder) are
free from significant pathology.8 If such concurrent pathol-
ogy exists, the owner should be aware of its significance and
possible effects on the outcome. Depending on its severity,
osteochondrosis of the neck and stifle (see Chapter 51) can
be treated concurrently or during separate surgical sessions
with little significant change in the prognosis.

EXPECTATIONS OF SURGERY
It is important to understand the owner’s expectations and
desires in regard to the surgical intervention, and to put
them into the context of what is possible. Owner com-
pliance and commitment prior to surgery is essential. Some
surgeons refuse to operate on a horse if the owner is not a
willing participant. Owners must be completely informed of
the risks, liability, and responsibilities of their decision.
Their goals must be tempered with realism. Trainers and
owners need to be patient, because full recovery may take up
to 1 year or more, and a conscientious effort should be made
to condition the patient, using a slow, gradually increasing
training program. The majority of owners want to have
horses that are capable of competing at high levels, even
though they were initially emphatic about being satisfied
with a pleasure horse or breeding animal. Interestingly, a
long-term evaluation done 1 to 4 years after surgery revealed
that as many as 90% of clients and referring veterinarians
were satisfied with the outcome.8

Although some horses with grade 3 or 4 ataxia have gone
on to race at a moderate level postoperatively, the per-
centage is low. It is possible for a horse with a grade 3 (out
of 5) ataxia that has had clinical signs for only 2 to 3 weeks
and only a single lesion present in severe flexion to return
postoperatively to a barely detectable ataxic state and, there-
fore, to be able to compete. However, all other factors such
as soundness, mental suitability, and overall health must be
considered also. It is disappointing when horses that have
undergone surgical correction do not recover enough to be
handled safely or cannot be placed in a large pasture with-
out extra observation. A mare should be able to stand for
service; a stallion should be able to cover a mare naturally
with only moderate assistance.

Based on an analysis of long-term results of 126
horses that had undergone ventral interbody fusion using
theSeattle Slew implant (see later) between 2000 and 2003,
88% of the animals recovered at least 1 grade, and 60% are
ridden successfully; 10% are used for breeding or were
retired.5

SURGICAL APPROACHES AND TECHNIQUES
Ventral Interbody Fusion
The most frequently used technique today is a modifica-
tion of the one developed by Cloward for use in humans.2,6,9,10
This modification uses a threaded or partially threaded
titanium implant that has multiple holes and an open end
that leaves an isthmus of bone in the center to encourage
faster fusion and reduce postoperative fractures and implant
migration (Fig. 52-4).

Preoperative Medications
Preoperative antibiotics consisting of procaine penicillin
gentamicin are administered to the animal before
induction of anesthesia, after surgery, and for the following
72 hours. Nonsteroidal anti-inflammatory drugs (NSAIDs),
such as phenylbutazone or flunixin meglumine, are admin-
istered at therapeutic levels before induction and are con-
tinued as long as needed. Tetanus toxoid is routinely
administered.
Prior to induction, an endoscopic examination of the upper airways is performed for detection of laryngeal hemiplegia. If this condition is identified, modifications should be made to the surgical approach, or the risk for bilateral laryngeal paralysis may be increased.

Anesthesia is begun with administration of xylazine, diazepam, or ketamine. Ataxic horses often show the desired effects with minimal doses of xylazine. Induction and recovery may be improved by slightly increasing the dose of diazepam.

Anesthesia
Positive-pressure-assisted inhalation of halothane, isoflurane, or sevoflurane is the preferred method of maintaining anesthesia, because it allows the surgeon to be minimally concerned for the horse’s life while drilling close to the spinal cord. Some surgeons have performed this procedure with a thiopental drip regimen with apparently good success. This technique requires an extremely efficient surgical method and practiced support personnel.

Common anesthesia problems are hypoxia, hypotension, and, because of the location of the surgical site, variable blood pressure readings if a facial artery is used (the authors recommend using the left facial artery, because the right carotid artery can be compressed with retractors during the procedure). Awareness of these possible complications allows early use of inotropic drugs; frequent arterial blood gas analyses and high oxygen flow rates should enable the anesthesiologist to react accordingly.

Patient Positioning
The animal is placed in dorsal recumbency, with the forelimbs tied in a moderately flexed position to allow adequate lateral stability without the excessive tension that could produce radial nerve dysfunction. A curved, heavy, 30-cm block of wood or metal is placed under the affected area (Fig. 52-5). The block helps with the extension of the cervical articulations and, at the same time, provides a stable surface to reduce excessive movement during drilling.

Identification of Surgical Site
The surgical site is identified after the ventral cervical area has been clipped, shaved, and disinfected. One or more 14-gauge needles are placed over the affected site and the articulation just cranial to it, and lateromedial radiographic projections are taken. The usual method of determining placement of the needles is to measure one hand width for each vertebra retrograde from the easily palpable wings.
of the atlas (Fig. 52-6). The needles should be placed on the side of the neck closest to the x-ray cassette to avoid any undue distortion resulting from parallax, especially with smaller animals. Once it has been determined that the needles are at the correct level, preparation of the surgical site is completed and the entire horse is draped. The use of suction or electrocautery is not necessary, but both reduce intraoperative time. For intraoperative imaging and evaluation, the use of a C-arm is recommended, because it avoids delays for film development.

**Surgical Technique**

A 20-cm skin incision is used for a single-level fusion centered over the pre-placed needles. A towel clamp placed at this level serves as a landmark and obviates the need to constantly palpate through two or three levels of draping and towels to ensure the correct anatomic location. After the initial skin incision is made, the cutaneous musculature is incised with a scalpel blade. Skin and subcutaneous hemorrhaging is controlled with hemostats, ligatures, and hemoclips. The sternothyroideus muscles are separated longitudinally at their junction down to the trachea, and additional hemorrhage is controlled as needed. Once the trachea has been identified, blunt dissection is continued down the right side of the trachea, using scissors or sterile-gloved fingers, and exposure of the longus colli muscles, lying directly beneath the trachea and the carotid sheath, is rapidly achieved. Application of hand-held Deaver retractors by an assistant allows palpation of the ventral spines through the longus colli muscles. The recurrent laryngeal nerve must be identified and protected from excessive retraction or trauma.

Usually, the ventral spinous processes (not present at C6-7) are readily identified. After making a 4-cm longitudinal midline incision over the ventral spine of the vertebra just cranial to the instability, the longus colli muscles are reflected from both sides with an osteotome or heavy dissection scissors. Self-retaining Inge retractors provide the best exposure of the ventral spine and reduce the effort needed from the assistant. The ventral spinous process is removed with a curved hand-osteotome and mallet down to the level of the body of the cervical vertebra. Bone hemorrhage is controlled with suction and with compression with sponges. The epiphyseal lines of the caudal aspect of the cranial vertebra can subsequently be identified.

A 16-mm drill guide is placed on the spine with its caudal surface on the old epiphyseal scar. Using a 16-mm drill, a test hole is drilled to a depth of 10 mm. A Hudson brace can be used, but a power reamer produces a more uniform hole. After the drill guide and drill are removed, it is usually easy to see the characteristic drab-white appearance of the intervertebral disc material. K-wires are then placed into the cranial and caudal aspects of the test hole, and an intraoperative radiograph is taken to assist in the placement of the 25-mm drill guide. Ideally, the drill guide should be perpendicular to the spinal canal and placed so that the joint space at the spinal canal is in the center of (or slightly caudal to) the guide (Fig. 52-7). Once this placement has been determined, the drill guide is hammered securely into place.

Using power equipment, the implant site is prepared by drilling with a series of drills starting with a narrow core saw, followed by a thicker core saw (Fig. 52-8) and a solid 25-mm drill to a depth of 15 mm. The implant site is initially widened with a no. 1 Kerf Cutter and followed by removal of the drill guide to allow the slightly larger no. 2 Kerf Cutter to finish the implant site to the desired depth (Fig. 52-9). This depth is usually 8 to 10 mm distant from the spinal canal. It has been the authors’ experience that this shelf of bone should be left between the bottom of the hole and the spinal canal to provide overall strength to the articulation during the recovery process. It is important to use intraoperative imaging and repeated depth gauge measurements to confirm the proper depth. The approximate depth of the vertebral body can be determined on the preoperative radiographs, remembering that 1 or 2 mm of the enlargement has resulted from parallax. The depth of the drill hole may vary with the age of the patient. The drilling should be done by only one person, whose responsibility is to focus on the depth.

After the depth has been reached, the implant site is tapped with a large tap that matches the partially threaded
Kerf implant. The implant is inserted until firm resistance is encountered (Fig. 52-10). A Hall drill is used to remove as much disc as possible to provide a bleeding surface of bone to encourage rapid acceptance of the bone graft. Bone graft material is prepared from the bone that is removed from the ventral spine and by the drilling process; the preparation involves dividing the dark red cancellous bone into small pieces. Small pieces of disc material, any periosteum, and excessive amounts of cortical bone should be excluded. The graft material should be covered with a blood-soaked sponge for optimal survival of the osteoblasts (see Chapter 82); it is not desirable to use saline, because its osmotic pressure may cause disruption of the osteoblasts. The graft is secured in place with gentle pressure from the handle end of a curette or osteotome. For a multilevel fusion, this procedure is repeated at the desired locations (Fig. 52-11).

After liberal flushing of the entire surgical area and a careful count of all foreign materials (e.g., surgical sponges), the self-retaining retractors are removed. Closure of the longus colli muscle is carried out with no. 0 polydioxanone (PDS) in a two-layer mattress pattern to reduce dead space. The remaining ventral cervical muscles are closed with no. 0 PDS in a simple-continuous or Ford interlocking pattern (the surgeon’s choice). No. 2-0 PDS is used on the subcutaneous tissue and staples on the skin. Application of drains is not essential. Even though seroma formation occurred in 4 of 126 cases, excessive seroma formation is a rare event. In over 600 cases, the cosmetic appearance of the surgical area has been very satisfying 4 to 6 weeks after surgery.
without the need for aspiration or drainage of any seroma. The incision is covered with a sterile towel or adhesive drape, and a postoperative radiograph is taken before removing the patient from the table so that there is a reference for any migration that might occur with a violent recovery.

**Recovery**

Recovery of these patients is an important aspect for a successful outcome. These ataxic patients are often unbroken, have had little handling, and will have some difficulty standing up under the best of circumstances. Violent recoveries are associated with migration of the implants and, as with most equine surgeries, anything that anesthetists and surgical personal can do to promote quiet, prolonged recoveries is beneficial. Hand recovery of all cases with a tail and head rope is important. The head rope must not be overused because of the likelihood that cervical traction will cause cervical fracture at the implant site. The head rope should be held by an experienced person who has respect for the dynamics of the surgery.

An extended period of recovery in lateral recumbency (40 to 90 minutes) is recommended. A combination of butorphanol and acepromazine in the early portions of the recovery to keep the horses comfortable and sensible has proved to be a good protocol. The onset of acepromazine is delayed compared with that of xylazine, so early administration is important, and excessive early movements can be directly controlled by the administration of very small xylazine dosages. Acepromazine has the advantage of inducing less severe ataxia than is produced by xylazine. Steroids are used only if the patient's ataxia is greater than grade 3-plus. Sling recoveries are sometimes necessary, especially for the patient with severe ataxia (grade greater than 3.5). Placing these candidates in the sling for 15 to 20 minutes a day for 1 to 2 days prior to surgery greatly enhances the usefulness of a sling postoperatively. Also, it is likely that if a sling was required after the myelogram, it will also be required after surgery. Older patients sometimes lie quietly for 75 minutes and then just stand up. A pool recovery system may not be indicated, because a compressive lesion at C6-7 may be disrupted as the head needs to be extended to keep from drowning.

After the patient is standing, a sterile dressing is applied to the incision site and is maintained with adhesive elastic tape applied in a circular fashion around the mane and neck. If there is a problem with stability and ataxia, a second dose of NSAIDs can be administered at this time. The patient should not return to the stall until the surgeon deems it stable enough to do so, and until the hallways leading to the stall are dry.

**Postoperative Management**

Postoperative antibiotic recommendations include penicillin or gentamicin intravenously for 3 days. NSAIDs (flunixin meglumine) are usually given intravenously for 3 days to reduce swelling and postoperative discomfort. Long-term oral use of NSAIDs (phenylbutazone), to reduce the cascading effect that compression causes in the spinal cord, is
also recommended. Information concerning the long-term effect of phenylbutazone on joint cartilage has resulted in modifying this recommendation, depending on the age and desired use of the patient.

Most patients are willing and eager to eat and move around. If possible, hay should be presented in a hanging net. Stretching the neck toward the floor is not ideal during the first week after surgery. The animal should be treated in the stall in a quiet, gentle manner to avoid sudden movements or falls. If the animal objects to intramuscular injections, switching to oral antibiotics and NSAIDs is indicated, or intravenous medications can be delivered by indwelling intravenous catheter. The bandage is left in place for the first 5 to 6 days postoperatively. It can be completely removed or replaced by a similar bandage if a good cosmetic appearance is desired in a short amount of time. The first 7 to 10 days after surgery are the most critical, so the animals are not walked out of the stall during this time.

A postoperative radiograph should be taken 4 to 5 days after surgery to evaluate any change in position of the implant. If there is any increase in swelling, discomfort, or ataxia, radiographs should be taken.

At least 45 days of stall confinement with a reduced caloric input is recommended to decrease the chance of some event occurring, such as a sudden fall, that would displace the implant. Hand-walking can start after 45 days. At 60 days, another radiograph and neurologic examination should be performed to help decide about increasing the amount of exercise and freedom. The fusion process is well underway at 60 days, and postoperative myelograms performed even on patients with static compression at C6-7 have normal dye columns at this time. The owner and trainer should be aware that the clinical signs will improve slowly for at least a year. Exercise will assist in retraining the spinal tracts. For the patients with greater than grade 2 ataxia, 4 to 6 month’s paddock exercise is indicated. For patients with less than grade 2 ataxia, walking can start after 45 days. The resulting structure cannot withstand the force of a violent recovery or a severe fall during the early postoperative period. In most instances, the only clinical signs associated with nondisplaced fractures are an increase in the rigidity of the neck. Severe fractures can result in clinical signs that range from paralysis (when displaced fragments cause severe cord compression) to obvious seroma formation and ventral displacement of the trachea as the implant migrates ventrally.

Fractures are confirmed by radiographic examination, although subtle fracture lines may be difficult to detect immediately, requiring repeat radiographs after 10 days. It may be necessary to perform a myelogram to determine whether the spinal canal diameter has been compromised.

Conservative treatment is indicated in most cases because revision with unstable vertebral bodies is very difficult, and the majority of cases resolve with the passage of time (Fig. 52-12).

Complication Rates

Minor complications associated with this procedure include ventral migration of the implant, laryngeal hemiplegia (LH), and Horner’s syndrome. Ventral migration was found on postoperative radiographs of 3.5% of patients and tended to occur within the first 7 days after surgery. The risk of LH was less than 1%, and transient Horner’s syndrome was observed in 1.5%. Fatal complications include esophageal rupture (1.5%), laryngospasm (0.8%), and fractures (0.8%).

Preliminary results show that the partially threaded Kerf cylinder implant procedure, if correctly performed, allows a faster fusion and reduces the chances of vertebral fractures and ventral migration, which has been associated with the Bagby Basket (Fig. 52-13).

Subtotal Dorsal Decompression Laminectomy

Indications

Subtotal dorsal decompression laminectomy, in which the dorsal caudal aspect of the cranial vertebra and the dorsal cranial aspect of the caudal vertebra are removed, is indicated
in cases of intramedullar or extramedullar enlargements with resulting cord compression, meningeal infiltration of metastatic malignant melanomas, presence of excessive synovial villi from the osteoarthritic facets, and hypertrophic dorsal lamina, resulting in extramedullar cord compression. Abscesses, parasitic granulomas, and intramedullar neoplasms may also be approached with this method if the diagnosis is reliable (Fig. 52-14).

Subtotal dorsal decompression laminectomy is not indicated for the removal of dorsal arches that result from fractures, or for the removal of dorsal arches that may play a part in cord compression resulting from the ankylosed hyperflexed joints seen in C2-3. There is even some question as to whether it is indicated for the presence of a hypertrophic dorsal longitudinal ligament or when disc material protrudes into the ventral aspect of the spinal canal.

**Surgical Positioning**

Once the decision has been made to perform a subtotal dorsal decompression, positioning of the patient is the most important factor contributing to the success or failure of the procedure. A number of surgical positions have been tried, including (1) placing the animal in ventral recumbency with all limbs flexed on a table and extending the head, (2) “hanging” the horse from the vertical surgical table under general anesthesia, and (3) placing the patient in a sling, inducing general anesthesia, and supplementing the suspension of the animal by locating the table under the sternum. Currently, the third method and a lateral recumbency
approach with the neck in full flexion are the most widely used. The choice of position usually rests with the surgeon, who should have practiced it (at least on several cadavers) prior to applying it to a clinical case.

**Preoperative Preparation**

Uneventful induction and recovery can be facilitated, especially in younger animals, if 2 or 3 days prior to surgery the animal can be accustomed to the use of a sling. The usual standard operative procedures of preventive medicine, including administration of anthelmintic medication and vaccination against upper respiratory infections, are strongly recommended to reduce the incidence of postoperative complications. The day before surgery, the mane is clipped and the animal is given a bath with a medicated shampoo. In addition, scrubbing of the dorsal neck surface with a bacteriostatic detergent is indicated. The perioperative use of NSAIDs and antibiotics is strongly recommended. The use of a depilatory agent 1 or 2 hours before surgery further aids in the removal of small hairs in the many creases of the dorsal aspect of the cervical arch. Some animals tend to show an inflammatory response to the depilatory agents, so these should be selected with caution.

**Surgical Technique**

After the animal is placed in the position most familiar to the surgeon, a large area extending from the summit to the intra-thoracic vertebrae (T4-5 to C2-3) is disinfected, draped, and toweled. A long incision (30 to 40 cm) is made through the usually thickened skin on the dorsal midline. After the initial profuse hemorrhage is controlled, the skin edges are toweled. Although it is not always necessary, application of the towels and towel clamps helps reduce any further capillary hemorrhage. Using a fresh scalpel blade, the subcutaneous tissue and fat overlying the funicular part of the ligamentum nuchae is sharply incised, exposing the dense white fibrous tissue of the ligamentum. Sometimes three or four small linear incisions are required to find the separation between the lamellar halves of the ligamentum nuchae, but as soon as this division is found, the two halves can be separated by blunt manual dissection. The incision needs to be of considerable length because of the depth of the field and the inelastic quality of the ligamentum nuchae. One or two sets of large, self-retaining retractors of the Finochietto or Balfour type will facilitate retraction in this area.

At this point, it should be possible to palpate the small spinal processes on the dorsal aspect of the vertebra. The location of the dorsal decompression at C6-7 is facilitated by palpating the 3- to 4-cm dorsal spinous process that often exists at the first thoracic vertebra. Radiographic markers (needles), applied before draping in the manner previously described, help confirm the proper location. The overlying epaxial muscles and soft tissues are removed from the dorsal arch with the combined use of periosteal elevators, large curettes, and rongeurs. The use of scalpel blades in this area should be avoided, if possible, because incising the many small blood vessels produces hemorrhage that is often difficult to control, greatly obscures vision, and increases the surgical time. After the soft tissue is removed from the vertebral arches, the white cortical bone is removed using a combination of a Hall drill, cranial drills, and rongeurs.

The original description advocated the use of Gigli wire inserted between one dorsal foramen and the next foramen. In the authors’ experience, horses with stenotic hypertrophic vertebrae often have no discernible dorsal foramina because they have been encroached on by the hypertrophic bone, and attempts to pass a Gigli wire as described is not recommended. It is important to remember that that the majority of these compressive lesions are the result of proliferation of dorsal bone, which is often much thicker than on normal specimens. This proliferative bone increases the surgical time, and it is important to be patient during the careful, tedious removal of this bone. A rapid, forceful puncture through the dorsal arch with an instrument can result in cord trauma that will exacerbate the already existing neurologic signs. A recommended technique is to identify the remains of any dorsal foramen and work cranially and caudally from this aspect with a Hall or cranial drill. After the inner cortical layer of bone appears, reverse-cutting rongeurs help remove the dorsal arch while protecting the cord. Proliferative or hypertrophic soft tissue arising from osteoarthritic articular facets can be removed with rongeurs and long scissors.

The appearance of epidural fat over the top of the bright, shiny dura indicates that decompression of the spinal cord
has been completed. Removal of the bone over the affected site must be adequate, especially on the caudal aspect. If cord compression was caused by a metastatic melanoma, all the discolored tissue should be removed. After the bone has been removed and the edges have been smoothed with a Hall drill, bone wax is applied to the bleeding edges of bone to reduce the amount of hemorrhage and the risk of clot formation around the spinal cord.

After careful inspection of the surgical site, all sponges and instruments are removed and a drain is secured into the tissues directly overlying the decompression site. The drain should exit through the lateral aspects of the cervical muscles. The drain is secured to the soft tissue surrounding the laminectomy with a 2-0 absorbable suture, which facilitates removal with gentle traction after 4 to 5 days.

With removal of the self-retaining retractors, the laminar portions of the ligamentum nuchae fall together and need to be apposed only on the most superficial aspect with a continuous Ford interlocking pattern using absorbable monofilament suture material. The funicular portion of the ligamentum nuchae, the subcutaneous tissue, and skin are all apposed using absorbable sutures in a continuous Ford interlocking pattern. Finally, stent bandages are applied to provide protection for the incision from excessive trauma that could occur during a violent recovery. Firmly applying bandages around the entire neck is discouraged, because this produces pressure that is directly transmitted to the exposed cord and can result in noticeable discomfort to the patient and increased ataxia.

**Postoperative Management and Aftercare**

Immediate postoperative management consists of antibiotics for 36 hours or longer, depending on surgical time and the possibility of breaks of aseptic technique during the procedure. The continued use of NSAIDs is indicated, especially in the severely ataxic patient, to reduce any sudden falls, because one of the more frequent complications of this procedure is fracture of the articular facets because of the destabilizing effect that the procedure has on the dorsal arches. The drain site should be continually bandaged or protected with antiseptic swabs and the drain left in place until there is a noticeable reduction in the amount of fluid obtained, usually 24 to 36 hours postoperatively. Hand-walking and resumption of physical therapy can begin within 10 days; the judgment of the surgeon or neurologist is the most important factor in determining this time.

Subtotal dorsal decompression laminectomy is not widely used because of its degree of difficulty, the amount of surgical time involved and surgical expertise required to perform it efficiently, and the development of a number of postoperative complications (e.g., articular facet fractures, compressive hematomas, and supplicative meningitis), which often result in the death of the patient.12,16

**REFERENCES**

Trauma to the spinal column in horses occurs most frequently in the cervical and thoracolumbar vertebrae, and the reported incidence varies. Vertebral fractures may be present with or without neurologic signs, depending on the area of the spine and the portion of the vertebra that sustains the trauma. Confirming a diagnosis of spinal trauma is complicated by the variation in clinical signs. Foals are more susceptible to vertebral fractures than adults, and the cervical vertebrae are more likely to be affected. The most common injuries in foals involve luxations, subluxations, and physeal separations of the cervical vertebrae. In adult horses, the injuries tend to involve both the cervical and the thoracolumbar regions.

Causes of spinal trauma include rearing and falling over backward, collisions with immovable objects, kicks from other horses, hyperflexion or hyperextension of the neck when falling, slipping on wet or muddy footing, and violently sitting backward on the ground or against solid objects. Injury to the spinal cord can occur without radiographic evidence of osseous damage, making the history of possible trauma important for arriving at a diagnosis.

This chapter describes the traumatic spinal injuries that are amenable to surgical correction, although in the horse the number is limited, for many reasons. The size of the horse presents unique technical challenges from a diagnostic and surgical standpoint, and it is difficult to maintain fracture fixation during the anesthetic recovery and rehabilitation period. Innovation is required during the surgical repair to achieve success, and there certainly are not many case reports in the literature from which to draw information when formulating a surgical plan.

TRAUMATIC INJURIES TO THE CERVICAL SPINE
Fracture of the Axial Dens with Atlantoaxial Subluxation

This injury is most commonly seen in foals younger than 6 months. The dens or odontoid process originates embryologically from the body of the first cervical vertebra and is attached to the axis by a physis. Fracture occurs when a foal falls with the neck in hyperflexion (somersaulting) or when the fall is violent, as in halter breaking incidents. The fracture most often occurs through the cranial physis of the axis, separating the dens from the body of the vertebrae. The dens remains attached by its ligaments to the atlas, and the axis moves ventrally. This results in cord compression at the atlantoaxial joint.

The degree of neurologic deficit depends on the degree and force of the spinal impact at the time of the injury. Neurologic deficits range from a stiff gait and splinted neck to total tetraparesis or even sudden death. In most cases, the foal becomes ambulatory almost immediately, with signs of neck splinting, ataxia, and tetraparesis developing gradually. Manipulation of the neck produces pain as well as palpable and audible crepitation. There may be an obvious axial malalignment in the atlantoaxial area. Lateral radiographs with the horse under sedation confirm the separation (widening) of the cranial physeal of the axis and cranioventral luxation of that vertebra. If ventrodorsal radiographs can be obtained, asymmetry in the atlantoaxial articulation may be noted.

The prognosis for recovery from this type of injury can be roughly correlated with the severity of the spinal cord injury and the degree of neurologic deficit.
damage. If there is motor function of all four limbs, with only paresis rather than paralysis, the prognosis for survival is favorable. If there is paralysis but the foal still shows conscious pain responses in all four limbs, the prognosis is guarded. If there is no conscious pain response, the prognosis is grave.

The method of treatment varies depending on the stability of the fracture and, to some extent, on the intended use of the horse. Nonsurgical management includes stall rest and the judicious use of anti-inflammatory drugs when foals exhibit splinting of the neck and relative instability at the atlantoaxial junction. Worsening of signs may become apparent if a fall occurs and further displacement of the axis relative to the atlas results. With time, a fibrous union of the dens to the axis may develop and the neurologic deficits will decrease. However, late-developing neurologic deterioration, in a patient that showed initial improvement, indicates that a proliferative bony callus or soft tissue hypertrophy is causing cord compression.

Surgical repair is warranted if deterioration in the foal’s clinical signs is noted, preferably before the foal becomes recumbent. Although the prognosis is guarded to poor if the foal is presented in recumbency, it may be improved with surgery. The goal of surgery is to provide decompression at the fracture site by realigning the vertebrae and providing stability with some form of fixation. Surgical techniques for repair of fracture-luxations include external fixation using Steinmann pins, compression plating, ventral atlantoaxial fusion, and dorsal laminectomy of the caudal atlas.3,6-8

One report described the placement of two, six-hole, broad dynamic compression plates on the ventral surface of the atlas and axis.6 The approach and exposure for this technique are the same as those described for ventral interbody fusion (Chapter 52). After exposing the ventral surfaces of the atlas and axis, the alignment of the vertebrae is corrected and maintained with bone-holding forceps. The ventral spinous processes are removed using rongeurs to create a smooth bed for the two plates. One plate is placed to each side of the midline and anchored using short, 4.5-mm cortex screws.

Another report described a ventral stabilization of the atlantoaxial junction by inserting two, 6.5-mm cancellous screws across the articulation after removal of cartilage from the articular surfaces. Removal of the fractured dens prior to stabilization is optional. Care must be taken during drilling of the screw holes in the vertebral arches of the atlas to avoid the spinal canal axially, and the vertebral arteries and first cervical nerves abaxially. A bone graft is placed in the articulation to promote fusion and a polyvinylidene plate is applied to the ventral surface of the atlas and axis to provide additional stability.3

In the first of these two reports, at 12 months after the surgery, ataxia was no longer apparent and radiography showed fusion of C1 to C2. One complication of surgery was right-sided laryngeal hemiplegia that did not resolve.6 The author of the second report warns of reduced lateral motion of the cranial portion of the neck after atlantoaxial fusion.3 Implants need be removed only if there is loosening or lysis of bone.

Various arrangements of Steinmann pins and variations in the application of Kirschner apparatuses in a through-and-through pattern have been reported. Four pins placed through the vertebral bodies of the atlas and axis, anchoring the dens with one pin and securing the pins with plates at the skin surface have been used. Care was taken to avoid the vertebral arteries. The animal recovered completely.8

**Atlantoaxial Subluxation and Luxation**

Subluxation of the atlantoaxial articulation, without fracture of the dens, is a rare condition seen in young horses up to 3½ years of age.3,5-11 The condition can be congenital in origin or the result of a traumatic incident. A combination of stretching or tearing of the ligamentous attachments of the dens and the fibrous atlantoaxial joint capsule leads to instability and spinal cord compression that is exacerbated with neck extension and relieved with flexion. The neurologic signs can be acute or chronic, and they vary in severity from mild ataxia to recumbency.11 The horse may have abnormal head and neck carriage and local swelling if the injury is acute, and it may resent neck manipulation. On plain radiographs, there may be a malalignment of the atlas and axis and, possibly, bony changes of the atlas secondary to trauma. On the extended views, further evidence of subluxation is a lengthening of the space between the articular surfaces of the atlas and the axis ventrally, whereas the space between the dorsal arch of the atlas and the spinous process of the axis is shortened.3,7 The spinal cord compression is documented with myelography. Computed tomography (CT) scanning of the atlas and axis may help in further defining the nature of the luxation.

Complete luxation of the atlantoaxial articulation resulting in displacement of the dens so that it lies ventral to the atlas is very rare (Figs. 53-2 through 53-5). For a complete luxation to develop, there needs to be complete disruption of the ligamentous attachments of the dens. Reportedly, horses with atlantoaxial luxation may have some stiffness of the neck but relatively few neurologic deficits.3 The diagnosis is confirmed by radiography. With the horse under general anesthesia, efforts can be made to reduce the luxation with head and neck manipulation, but this is likely to be successful only if the injury is acute.7 In foals, there is also a significant risk of traumatizing the spinal cord during the reduction attempts.

Horses with atlantoaxial subluxation can be successfully treated with subtotal dorsal laminectomy3,11 (see “Subtotal Dorsal Decompression Laminctomy,” in Chapter 52). Surgery is certainly recommended if the horse is showing neurologic deterioration or if neurologic deficits persist despite conservative treatment. Removing the caudal two thirds of the dorsal arch of the atlas relieves the spinal cord compression and allows the range of motion of the atlantoaxial articulation to be maintained. A portion of the dorsal atlantoaxial ligament is left intact. Although the compression may be relieved, persistent instability represents a potential threat for several weeks after surgery. In a report of four horses with atlantoaxial subluxation treated with dorsal laminectomy, two horses recovered completely and a third showed satisfactory improvement. One was lost to follow-up. No surgical treatment has been reported for complete atlantoaxial luxation.
Fractures of the Atlas and the Axis

Fractures involving the atlas and the axis (other than fractures of the dens) occur occasionally. Fractures of the atlas produce neck pain and stiffness, but the degree of ataxia depends on the nature of the fracture and the degree of spinal cord impingement. In some patients, there are no neurologic deficits associated with a fracture of the atlas. Standing radiographs, including a dorsoventral view, are used to make a definitive diagnosis. In the foal, the growth plates and their closure times must be taken into consideration when interpreting the films.12

Fracture of the ventral arch of the atlas and disruption of the ligaments that secure the dens can lead to the formation of a bony callus that impinges on the vertebral canal and produces a later onset of ataxia.3 Myelography and, if available, CT scanning should subsequently be performed to further document and evaluate the nature of the compression. A dorsal laminectomy of the caudal half to two thirds of the dorsal arch of the atlas can relieve the spinal cord compression created by the fracture callus and may result in a long-term improvement in the neurologic status of the horse.3 Fractures of the axis (other than those involving the dens) occur but reports of surgical repair are rare.2,3 There is a case report of a successful lag screw fixation of an oblique fracture of the body of C2 in a yearling warmblood stallion that was accomplished with the aid of computed tomography.13

Cervical Vertebral Fractures (C3 to C7)

Cervical spinal fractures in the adult horse are rare, but of the spinal fractures reported in the horse approximately 50% involved the cervical vertebrae.2,4,5,13 Compression
Fractures of the vertebral body are most frequently diagnosed, followed by articular facet fractures. These injuries result from head-on collisions or falling over jumps or obstacles. Falls in which the neck is severely hyperextended can result in fracture through the ventral half of the caudal end plate of the vertebral body. The ventral portion of the epiphysis remains attached to the caudal vertebra by the strong fibrocartilaginous disc (Fig. 53-6). The caudal cervical vertebral body physes in horses are not closed until 4 to 5 years of age, although, practically, the cranial and caudal physes do not separate from the vertebral body in fractures or luxations after the horse is 2 years old. If trauma is severe, pedicles of the caudal facets fracture and elevate, effectively de-roofing the spinal canal (Fig. 53-7, and see Fig. 53-6). Although the fractures can produce severe angulation of the spine, the neurologic effects are diminished as a result of the de-roofing.

Cervical vertebral body fractures can also occur after intervertebral stabilization, particularly at C5-6 and C6-7 (regardless of the fusion technique).

Clinical signs depend on the degree of bony disruption and instability at the fracture site, and on the severity of the trauma to the cord. If the fracture is displaced and the spinal cord is compressed, neurologic signs vary from mild ataxia to quadriplegia and, in some cases, sudden death. Because of damage to the central portion of the spinal cord with trauma, the innervation to the forelimbs is severely affected. When compression involves dorsal nerve roots, pain and torticollis are the principal signs. Sympathetic dysfunction, exhibited by Horner’s syndrome and skin hyperthermia, may be present.

The diagnosis of cervical vertebral fracture is confirmed by radiography. However, it can be very difficult in thick-necked horses, even if the horse is in lateral recumbency, to get diagnostic radiographs if there is minimal disruption of the fracture fragments or there is a great deal of swelling in the neck. Fracture lines may be poorly visualized. If the horse is standing, every effort should be made to get diagnostic standing radiographs. This allows a diagnosis without sub-
jecting the horse to anesthesia and recovery, which may displace the fracture fragments, causing more damage to the spinal cord. If the horse is already recumbent, or there is progressive neurologic deterioration despite aggressive medical therapy, the horse can be anesthetized to obtain the radiographs. High-quality radiographs, including oblique and ventrodorsal views, or CT scans are necessary to gain an appreciation for the fracture configuration, particularly of vertebral body fractures where there can be multiple fracture lines and minimal displacement. The more distal portion of the neck (C5 to C7) in a large horse may be too large to be accommodated by the portal of the CT scanner. If more than one vertebra is fractured, a myelogram may be useful to determine the site or sites of spinal cord compression. When the fracture is amenable to some form of fixation, the surgeon must be prepared to immediately follow the radiographic studies with the surgical repair. The risk of further spinal cord damage if the horse is allowed to recover and be repaired at a later date is too great.

If the horse remains standing and is not showing progressive deterioration, conservative treatment is usually the treatment of choice. Some horses with pedicle fracture(s) experience further neurologic deterioration, with the formation of a healing callus that impinges on the dorsolateral aspect of the spinal canal causing cord compression (Figs. 53-8 and 53-9). Horses with an articular facet fracture can also develop torticollis that becomes permanent as a result of vertebral malalignment. There is a report of coaptation cast application used successfully to immobilize noncomminuted proximal cervical vertebral fractures in foals. These types of casts can be difficult to apply properly and safely.

If enough intact bone exists in the vertebral body to allow secure implant fixation, some types of recent fractures can be realigned and stabilized with screws or with plate and screw fixation, possibly in combination with ventral intervertebral stabilization. Each case needs to be considered on its own merit with regard to the type of fixation required for a successful repair. Intraoperative radiographic control of the drilling depth and screw positioning is critical to avoid penetration of the vertebral canal. It is difficult to get a secure screw purchase in vertebral bone, particularly in foals. There is a report of a successful repair of a cranial articular process and lateral neural arch fracture of C4 using a combination of an intervertebral fusion procedure followed by the ventral application of a broad DC plate that spanned the bodies of C3 and C4. The prognosis for recovery from any form of surgical repair is related directly to the severity of the initial neurologic deficits and the long-term stability of the repair.

In horses that have pedicle fractures that develop exuberant bony callus impinging on the spinal canal or the lateral foramen, signs of spinal cord compression or nerve root impingement may develop. One author suggests that surgical intervention is indicated, in the form of either a dorsal laminectomy or a ventral stabilization. Removal of the dorsal lamina and reduction of the bony callus at the compressed site produces immediate decompression, but the procedure is difficult and tedious, and there is a risk of refracture of the affected pedicle and worsening of the neurologic signs as a result of surgical trauma. Ventral intervertebral fusion leads to reduction in the size of the articular facets and the bony callus over a 3-month period after the surgery. Although there is not an immediate decompression, as produced with dorsal laminectomy, there is much less risk associated with the surgery.

**Figure 53-8.** Standing oblique lateral radiograph of the C5-6 articulation in a yearling. There is severe proliferative remodeling of the articular processes at C5-6. Lateralization of the observed remodeling could not be determined radiographically.

**Figure 53-9.** Transverse computed tomographic image through the cranial aspect of C6 after myelography. Severe degenerative remodeling and subchondral cystic change of the articular processes of C5-6 is seen on the left. Mild remodeling and subchondral cystic change is also seen at the axial aspect of the C5-6 articulation on the right. The spinal cord is outlined by a contrast-filled subarachnoid space. Note the left-sided, dorsal compression of the spinal cord secondary to the articular process remodeling.

**TRAUMATIC INJURIES TO THE THORACOLUMBAR SPINE**

Thoracolumbar vertebral injuries are more common in adult horses than in foals. Horses that engage in jumping activities are most often affected with life-threatening vertebral fractures. The incidence of these types of lesions cannot be accurately assessed because some fractures are never identified. For instance, in many racing jurisdictions, it is not mandatory to perform postmortem examinations on those horses that are euthanized at the racetrack. Fracture of the thoracic dorsal spinal processes is often associated with the
horse rearing, falling backward, and striking the withers. In a report of 22 cases of thoracolumbar vertebral fractures, 15 involved the vertebral body or neural arch and produced severe neurologic signs that necessitated euthanasia. The remaining seven horses had fractures of the dorsal spinous processes and exhibited no neurologic signs.\(^3\) The more common sites of fracture of vertebral bodies include the first three thoracic vertebrae, around T12 (the area of greatest lateral bending and axial rotation), and the lumbar vertebrae.\(^16\) Dorsal spinous process fractures tend to occur at or near T6. In a foal, a thoracic vertebral body fracture occurred at T11 after an electric shock.\(^17\) Abscess formation in the vertebral body as a result of septicemia in foals can predispose to fracture.

The clinical signs associated with a thoracolumbar vertebral fracture depend on the portion of the vertebra that is fractured and the degree of bony disruption. Severe compressive fracture of the vertebral body may result in paraplegia if the fragments displace, in delayed onset of paraplegia if the fragments do not displace until after continued movement, and, finally, in no paraplegia if displacement remains minimal. Only the group with little or no displacement of fragments has a chance of total recovery with conservative management.

The diagnosis of a thoracolumbar vertebral body fracture in an adult horse is complicated by the fact that radiography of this area is generally unrewarding because of the massive musculature around the vertebrae. The clinician must often rely on the physical examination and neuroanatomic localization of the lesion to make a presumptive diagnosis. In the horse with a healing fracture, scintigraphy may be useful for localizing the affected vertebra. In foals, CT scanning can be used to assess the thoracolumbar spine, and myelography is used to document the extent of the spinal cord compression—information that is necessary for determining the length of decompression required if a dorsal laminectomy is being considered.\(^4\)

Thoracolumbar laminectomy and fracture stabilization has been described in the foal and should be attempted only if the foal has evidence of deep pain recognition or some voluntary movement of the hindlimbs.\(^5\) A dorsal laminectomy of the affected area is performed with the foal in sternal recumbency. Steinmann pins are placed into the adjacent vertebral bodies, the vertebrae are manipulated into alignment, and polyvinylidene plates are applied to the dorsal spinous processes. Polymethylmethacrylate is used to connect the pins and produce rigid fixation. The plates and pin fixation are removed in 3 to 6 months. The author stated that the prognosis for foals with thoracolumbar fractures is generally grave, although surgical treatment may improve the outcome in selected cases.\(^1\) Adult horses that are recumbent and have severe neurologic signs as a result of thoracolumbar spinal fracture are euthanized. In those horses where the signs are limited to back pain and rear limb incoordination, conservative management can be successful.\(^15\)

The diagnosis of fracture of the dorsal spinous processes is not difficult. The height of the spine is decreased, because the most proximal aspect of the spine fractures and moves laterally. The area becomes swollen and painful to the touch. Radiographs are helpful in confirming fractures of the dorsal spines and the extent of the damage (Fig. 53-10).

Fractures of the dorsal spines usually do not require surgery unless the bone fragments become sequestered or their position, after fracture, precludes the use of a saddle. A defect in the withers area may necessitate a special saddle pad. If surgery is required or elected, the same procedure used for treatment of overriding dorsal spinous processes is employed.\(^18\)

With the horse in lateral recumbency and the displaced processes uppermost, a long, slightly curved incision is centered over the fragments. The incision extends through the skin, the subcutis, and the supraspinous ligament. Bone fragments are identified and removed by freeing them from underlying muscle and ligamentous attachments. If the bone has sequestered or if infection is present, appropriate drainage exits are created to facilitate gravitational drainage. The area will heal enough to resume riding after 8 to 12 weeks; however, special saddle pads may need to be used to prevent abrasion by the saddle. Internal fixation of spinous process fractures with plates and screws has been performed, but the procedure carries the risk of prolonged anesthetic time and a difficult recovery from anesthesia.

**TRAUMATIC INJURIES TO THE SACRAL SPINE**

Trauma to the sacral area occurs when the horse suddenly dog-sits or falls over backward, landing on the croup area.\(^20\) Subluxation where the sacrum articulates with the iliac crests causes chronic pain that may originate with one traumatic event or may be caused by repetitive jarring of the spine in this area during work. Compressive lesions of the sacrum involve the cauda equina with loss of function to the sacral and caudal nerve roots and the pudendal, caudal, and parasympathetic pelvic nerves that originate from these nerve roots.\(^2\) The resultant clinical signs include pain and swelling over the croup and tail head, tail weakness or paralysis, decreased anal tone, retention of feces, bladder distention, and urine dribbling. There may be analgesia of the tail, anus, and perineal region, and the surface of the penis in males. The diagnosis of a sacral compressive lesion is based on the clinical signs, palpation of the sacral area per rectum, radiography, and, if the horse is small enough, CT scanning.\(^3,22\) Scintigraphy may be useful for initially
localizing an injury to the sacrum. More extensive injuries that involve the caudal lumbar and sacral regions can produce marked hind limb weakness, ataxia, and neurogenic muscle atrophy of the hindquarters. This may be documented by electromyography and muscle biopsy.

Acute injury should be treated with anti-inflammatory drugs, and up to 10 days should be allowed for signs of recovery. During this time, evacuation of the rectum several times daily and topical treatment of the tail and perineal region to prevent scalding is part of the management required. If there is no improvement within 10 days, the prognosis is unfavorable for recovery, and either surgical intervention or euthanasia should be considered. Surgical decompression of the sacrum can be achieved by removing the spinous processes and dorsal laminae of the sacral vertebrae. Even with surgery, the prognosis is guarded. In acute cases, stabilization after decompression is necessary and can be accomplished by using plates and screws. In foals where stabilization was accomplished using long plates attached to dorsal spinous processes, the plates must be removed within months of the repair to prevent development of lordosis in the lumbosacral region.

One of the authors examined a 6-week-old foal that had a compressive spinal lesion at L6 and S1 as a result of trauma at birth. The foal underwent a dorsal decompression of L6 and S1 and there was some improvement in clinical signs after surgery. A follow-up CT scan 4 months after surgery showed good decompression at the dorsal laminectomy site, but stenosis of several of the nerve root canals probably contributed to the ongoing muscle weakness. To date, some 5 years after surgery, the horse has residual ataxia and muscle weakness but has learned to adapt remarkably well as a nonathletic companion animal. In horses with persistent tail paralysis, the tail may need to be amputated.

## Traumatic Injuries to the Coccygeal Vertebrae

Horses have an average of 18 coccygeal vertebrae. Trauma to the more distal vertebrae may well go unnoticed. Coccygeal fractures generally occur as a result of the horse falling back onto the tail or backing into an immovable object. Other causes of tail injury include entrapment in a door, bite wounds by other animals, and improperly placed tail wraps. If the tail distal to the site of trauma loses its blood supply, necrosis occurs, requiring amputation.

Trauma to the base of the tail (Cry 1 to 3) may cause fracture to the vertebral as well as soft tissue injury, and neuropaxia of the motor nerves in this area. In most horses, the fractures are closed, but the fracture may be comminuted with displacement of the fracture fragments. The nerve injury can result in an inability to move the tail and defecate properly. Urine (in females) and fecal scalds can develop. Muscle atrophy over the tail head is consistent with neurogenic atrophy. Manipulation of the tail produces pain, and there is palpable crepitation at the tail base. Distal to the lesion there is loss of motor function. Lateral or oblique lateral radiographs confirm the presence of a vertebral fracture. Nuclear scintigraphy may be useful for identifying concurrent bony trauma, such as a sacral fracture.

Most horses with fractures of the coccygeal vertebrae are managed conservatively with stall rest and the use of anti-inflammatory drugs. The fractures can be relatively slow to heal, and there may be permanent neurologic damage as well as conformational changes as a result of the muscle atrophy and callus formation. Some form of stabilization or fixation, such as the placement of Steinmann pins across the fracture or the use of the pinless external fixator (see Chapters 81 and 103), might hasten healing and reduce the irritation to nerves in the area, thereby allowing a quicker return of tail function.

ETIOLOGY AND PATHOGENESIS

Mechanical injuries to peripheral nerves occur because of compression, entrapment, transection, laceration, ischemia, crushing, stretching, and chemical or burn damage.1,2 These injuries are usually categorized according to the degree of damage to a single axon. However, compound nerves contain numerous fascicles, and each fascicle is made up of many axons within a connective tissue sheath. The functional effect of damage is seldom as straightforward as single-fiber classifications would suggest, and usually reflects differing degrees of damage across a nerve.

Damage to individual axons fall into two major functional categories. Type 1 injury refers to loss of function without loss of axonal continuity. Type 2 injury represents damage to axonal structures such that Wallerian degeneration of the axon ensues distal to the site of injury; the proximal axonal segment and the cell body remain intact. Retrograde degeneration of the proximal nerve occurs if connectivity is not reestablished. A well-accepted classification system that divides the spectrum of injury into five categories3 is shown in Figure 54-1.

Type 1 or neurapractic lesions are characterized by a failure of conduction of the action potential across the injured axonal segment.4 Normal muscle action potentials are evoked by stimulation of the nerve anywhere distal to the lesion, but they are absent when the nerve is stimulated proximal to the injury. The pathologic basis for these reversible injuries could be nerve compression, damage to the myelin sheath, or alteration of the functions of the axonal cell membrane or its channel proteins.

Type 2 injuries are characterized by axonal interruption, or axonotmesis. This is equivalent to the Sunderland type II injury. If there is disruption of components of the connective tissue sheath and axon, the process is termed neurotmesis. According to the Sunderland classification system, there are three grades of neurotmesis (III, IV, and V), reflecting disruption of endoneurium, perineurium, and epineurium. Recovery by axonal regrowth is unlikely after neurotmesis.5 Immediately after axonotmetic injury, the distal axonal segment is competent to conduct action potentials; however, within 3 to 8 days after injury, the distal segment degrades and no longer responds to electrical stimulation. In this way, neurapractic (type 1) and axonotmetic (type 2) injuries of greater than 8 days' duration can theoretically be distinguished. Longstanding axonotmetic injuries result in retrograde degeneration of the neuronal cell body and secondary demyelination of the proximal axonal segment. After axonotmesis of motor nerves, muscle reinnervation occurs by two separate mechanisms: collateral sprouting and axonal regrowth.1 If there is incomplete loss of axons to a muscle, surviving motor axons generate sprouts from their nerve terminals, which can establish competent junctions with adjacent denervated muscle units. Reinnervation of muscle units by this process occurs within days to weeks. However, if the motor axons to a muscle are severed, reinnervation occurs by growth of collateral sprouts from the proximal stump. Axonal sprouts grow at a rate of 1 mm per day (approximately 1 inch per month). Regeneration occurs under the influence of growth factors including neurotrophic growth factor, brain-derived neurotrophic factor, and ciliary neurotrophic factor.6 Successful reinnervation thus may take many months. Because of progressive fibrous replacement of denervated muscle and retrograde degeneration of the proximal parts of affected motor neurons, it has been suggested that reinnervation may not be possible if more than 12 months have elapsed since the original injury. However, reinnervation surgery has been successful when performed on human patients 20 years or more after denervation.7

Large-diameter myelinated fibers are most sensitive to compression forces. The largest sensory axons, including afferent fibers conveying touch-pressure, vibration, and proprioception, are larger than motor axons and are usually damaged first.
CLINICAL SIGNS
Peripheral nerve injuries are characterized by weakness of the innervated muscle, accompanied within 2 to 4 weeks by appreciable atrophy. When the injured nerve supplies important extensor muscles of the limbs (e.g., radial, femoral, sciatic, peroneal), there is obvious alteration of gait. Areas of cutaneous anesthesia occasionally accompany peripheral nerve injuries. Over the neck and trunk, cutaneous sensory innervation occurs in defined bands associated with segmental dermatomes. Damage to a peripheral spinal nerve or dorsal nerve root results in cutaneous anesthesia/hypalgesia over the supplied dermatome. With damage to the pudendal nerve or its sacral nerve roots, there is anesthesia/hypalgesia of the perineal area. In contrast, relatively small autonomous zones have been defined for sensory components of the ulnar, musculocutaneous, median, femoral, tibial, and peroneal nerves (Fig. 54-2). Sympathetic fibers are distributed with peripheral nerves, so denervated skin also may be evident as circumscribed spontaneous sweating. The most common and important syndromes of mechanical injury to peripheral nerves of the limbs are described later.

Suprascapular Nerve
The suprascapular nerve arises from the 6th and 7th cervical spinal cord segments and courses laterally and ventrally between the supraspinatus and subscapularis muscles before coursing around the front of the scapula about 7 cm proximal to the scapular tuberosity and ramifying in the supraspinous and infraspinous fossae.

Suprascapular nerve injury occurs most commonly when a horse collides at speed with another horse or with inanimate objects, such as fences, trees, or doorways. It may also occur when a galloping horse stumbles over uneven ground. In each of these situations, there is likely to be stretching or direct compression (or both) of the suprascapular nerve as it curls around the front of the neck of the scapula under cover of the supraspinatus muscle. The muscles innervated by the suprascapular nerve, the supraspinatus and infraspinatus, normally provide lateral support for the shoulder joint. Consequently, when the nerve is injured, there immediately is laxity and lateral instability of the shoulder joint, which bows out or “pops” as the affected limb bears weight. Although subluxation of the shoulder joint does occur after the suprascapular nerve is blocked at the scapular neck, it has been suggested that other nerves (e.g., axillary, pectoral, subscapular, brachial plexus roots) and muscles (e.g., pectoral, subclavius, subscapularis) are usually damaged with this type of injury, thus contributing to shoulder instability and subluxation. Within 2 to 4 weeks of injury, there is obvious atrophy of the supraspinatus and infraspinatus muscles. Wasting of these muscles becomes complete over the ensuing several months. The condition is known as sweeney.

Neuapractic damage to the suprascapular nerve should heal within several days to several weeks. After partial nerve damage, sprouts from the neuromuscular terminals of surviving fibers should find denervated muscle and restore function within several weeks. In either of these settings (neuapraxia or partial nerve damage), severe muscle atrophy should not occur before recovery begins. More complete axonal injury results in sweeney, and any recovery depends on regrowth of axonal sprouts from the proximal stump of the suprascapular nerve. Successful reinnervation is evident as recovery of muscle bulk in the ventral part of the

supraspinatus muscle beginning within 3 months of injury. Maximal recovery takes an additional 3 to 12 months. Regrowth of the suprascapular nerve can be facilitated by surgery to resect scar tissue (external neurolysis) and reduce tension on the nerve as it crosses the front of the scapula (see Chapter 98). The surgery can either be performed preemptively when soft tissue swelling has subsided, or 3 to 6 months after injury when it is clear that spontaneous reinnervation is not occurring.

Radial Nerve

The radial nerve innervates a flexor of the shoulder and the extensors of the elbow, carpal, and digital joints. It arises chiefly from the 1st thoracic root of the brachial plexus. The nerve travels for a short distance with the ulnar nerve as it passes between the long and medial heads of the triceps. From there, it winds downward and outward around the humerus in the musculospiral groove, crosses the lateral aspect of the elbow joint, and ramifies in the extensor muscles of the digit.

The nerve is well protected by surrounding muscles and therefore not normally damaged unless there is severe injury to adjacent tissues. The T1 nerve root may be lacerated by fracture of the C7 or T1 vertebra or the first rib. Likewise, the proximal part of the nerve is commonly damaged as a result of humeral fracture. The radial nerve (or the roots that form it) may be injured with other components of the brachial plexus by trauma to the shoulder region. Rarely, the nerve is injured when the upper leg gets wedged (e.g., in a tub or between the rails of a fence) and the horse struggles to release it. The radial nerve and triceps muscles are vulnerable to damage when horses are positioned in lateral recumbency, usually under general anesthesia. The risk is particularly high in large, muscular horses on poorly padded recumbency, usually under general anesthesia. The risk increases with the duration of the procedure. Experimental studies have shown that ½ to 1 hour of ischemia produces neurapractic conduction failure, and greater than 3 hours of ischemia causes permanent changes. In horses with complete radial paralysis stand with the shoulder extended and the rest of the joints flexed. The elbow is “dropped” (i.e., lower than normal) and the dorsal surface of the hoof rests on the ground. When forced to walk, the horse may partially protract the limb by exaggerated extension of the shoulder; however, the toe drags and the horse collapses on the limb during the weight-bearing phase of the stride. If the site of damage is distal to the branches to the heads of the triceps (middle third of the humerus), the shoulder is held in normal position and the elbow is not usually dropped. Such horses can bear weight if the hoof is placed flat on the ground. If reflexes can be tested while the horse is recumbent, it is expected that the triceps reflex will be absent but the flexor (withdrawal) reflex will be normal.

Although the radial nerve has numerous cutaneous sensory branches, injury to this nerve does not result in any consistent area of cutaneous anesthesia.

Beginning at 2 to 4 weeks, there is progressive atrophy of the extensor muscles of the limb distal to the site of injury. The principles just described for neurapractic and axonotmetic injuries apply. With regrowth of axonal sprouts from the proximal stump of the radial nerve, the triceps muscle is expected to recover function before the digital extensors.

Musculocutaneous Nerve

The musculocutaneous nerve arises near the suprascapular nerve from the part of the brachial plexus supplied by the 7th and 8th cervical roots. It descends on the medial surface of the coracobrachialis muscle and forms a loop with the median nerve directly beneath the brachial artery before terminating in branches to the biceps brachii, pectoral, and brachialis muscles. The musculocutaneous nerve supplies flexors of the elbow.

Injury to the nerve is rare and causes only transient toe-dragging. The shoulder may be held in a flexed position and the elbow in an extended position. The diagnosis can be made by finding hypalgesia/anesthesia over the dorso-medial aspect of the carpal region and proximal metacarpus (see Fig. 54-2), beginning immediately after the injury, and by appreciating obvious atrophy of the biceps and brachialis muscles, beginning 2 to 4 weeks after injury. Injury to the musculocutaneous nerve eliminates the biceps reflex, although this reflex is difficult to obtain even in normal horses. The flexor reflex should be intact, although elbow flexion may be weak.

Median and Ulnar Nerves

The median nerve is the largest branch of the brachial plexus and receives input from the 8th cervical and 1st thoracic nerves. After exchanging fibers with the musculocutaneous nerve, it descends along the medial aspect of the leg in association with major arteries and terminates in palmar and cutaneous branches. The ulnar nerve arises from the thoracic part of the brachial plexus, passes downward and backward over the medial epicondyle of the humerus (deep to the medial head of the triceps), and passes along the palmar aspect of the metacarpus under cover of the digital flexors to terminate in branches that contribute to the lateral palmar nerve and cutaneous sensation. These nerves supply muscles that extend the elbow, and flex the carpus and digits.

Injury to either or both nerves can be caused by injury at the brachial plexus or along the medial aspect of the upper limb. Experimental section of the nerves causes an “tin soldier” gait, with decreased flexion and dragging of the toe during the protraction phase of the stride. There is hypalgesia/analgnesia of the skin of the caudal forearm, lateral metacarpus, and medial phalangeal areas. When flexor reflexes are tested by pinching the skin of an area with unimpaired sensation (e.g., over the lateral metacarpophalangeal [MCP] joint), there is an intact flexor response, but it is weak compared with the normal side. Even without recovery of nerve function, interference with gait at the walk decreases over time and is minimal by 3 months after the injury. The reason for this adaptation is unclear, although it has been suggested that fibers contributed by the musculocutaneous nerve may take over some of the functions from the median nerve. Atrophy of the carpal and digital flexor muscles is apparent after 2 to 4 weeks.
Femoral Nerve
The femoral nerve arises principally from the 4th and 5th lumbar nerve roots, courses backward and ventrally between the psoas major and minor muscles, and then runs between the sartorius and iliopsoas muscles lateral to the external iliac artery. It terminates as branches to the heads of the quadriceps. The saphenous nerve, a branch with both motor and sensory function, joins the femoral nerve at the point of emergence from the psoas muscles. The femoral nerve innervates muscles that flex the hip and extend the stifle.

The nerve courses too deeply to be directly affected by an external blow to the pelvic limb; however, it can be damaged by ilial, femoral, or vertebral fractures. Ischemic injury caused by prolonged stretch or increased tissue pressure during anesthesia in dorsal recumbency may cause bilateral femoral neuropaxia.16 A similar presentation, presumably caused by compression of nerve roots by the foal in the birth canal, is seen in mares after severe prolonged dystocia.

With unilateral paralysis of the femoral nerve, the pelvic limb adopts a flexed posture, usually with the foot flat on the ground. When the horse tries to bear weight, the limb buckles. During walking, there is obvious lameness, with a relatively brief and ineffectual weight-bearing phase over the affected limb. This can be quite subtle in horses with partial femoral nerve paralysis. In the case of bilateral involvement, the horse is either unable to rise or gets to its feet with difficulty, and then stands briefly and uncomfortably in a crouched position.

If the nerve injury occurs proximal to the saphenous branch, there is anesthesia/hypalgesia of the skin over the medial surface of the thigh (see Fig. 54-2). Atrophy of the quadriceps muscle is evident within 2 to 4 weeks. The flexor reflex should be normal, but the patellar reflex is weak or absent.

Sciatic Nerve
The sciatic nerve is the largest nerve in the body. It is derived principally from the 6th lumbar and 1st sacral nerves but also receives a branch from the 5th lumbar nerve. The nerve passes caudally and ventrally on the sacrosciatic ligament before turning between the greater trochanter and tuber ischii. It courses ventrally in the thigh between the biceps femoris laterally and the adductor, semimembranosus, and semitendinosus medially. It continues as the tibial and peroneal nerves. The sciatic nerve supplies important extensors of the hip and flexors of the stifle.

Sciatic nerve damage is usually a result of deep injections into the caudal thigh ventral to the greater trochanter. Such injections may injure the nerve by direct laceration, injection of material into the nerve, or through secondary inflammation or compression from scarring induced by previous deposition of the drug close to the nerve.1 In most cases, the neurologic deficits are apparent within a few minutes. A delayed onset suggests the development of perineurial or endoneurial inflammation or fibrosis. The nerve may also be injured by fractures of the ilium or ischium, or by sacroiliac and coxofemoral dislocations.

The posture of the affected limb is characteristic: it is held slightly caudal with the dorsum of the hoof resting on the ground. The stifle and tarsus are more extended than normal, whereas the distal joints are flexed. During walking, the leg is dragged forward by the actions of the quadriceps and biceps femoris muscles. These muscles, in concert with the reciprocal apparatus, allow the horse to bear some weight on the limb if the foot is first placed in normal position.

There is cutaneous hypalgesia/anesthesia over most of the limb except for the medial thigh. If the flexor reflex is tested by pinching the skin over the medial thigh, the response is intact, but weak compared with the normal side.

Peroneal Nerve
The peroneal nerve arises from the sciatic trunk deep to the biceps femoris and descends on the lateral head of the gastrocnemius. It crosses the lateral aspect of the femorotibial joint and terminates in superficial and deep branches, which course ventrally between the long and lateral digital extensors. The nerve provides motor innervation to the flexors of the tarsus and the extensors of the digit.

Paralysis results in extension of the tarsus and flexion of the distal joints of the pelvic limb. At rest, the limb is held slightly caudally with the distal joints in flexed position and the dorsum of the hoof contacting the ground. During walking, the limb is moved erratically. The toe is dragged along the ground during the weak protraction phase, and then pulled caudally as the horse attempts to bear weight. As is the case with sciatic involvement, the limb can support weight if the foot is placed in normal position.

There is progressive atrophy of the cranial tibial and long and lateral digital extensors and immediate cutaneous hypalgesia/anesthesia over the lateral metatarsus. The flexor reflex is intact and usually appears normal.

Tibial Nerve
The tibial nerve represents the direct continuation of the sciatic nerve. It runs between the bellies of the gastrocnemius muscle and passes distally on the medial aspect of the leg immediately dorsal to the superficial flexor tendon before terminating in the medial and lateral plantar nerves. The tibial nerve innervates the gastrocnemius (extensor of the tarsus) and digital flexors.

With tibial neuropathy, the resting limb is held more flexed than is normal and, although the foot contacts the ground in normal position, the MCP joint often partially collapses into a flexed position (i.e., "knuckles"). The foot is moved in stringhalt-like fashion, with exaggerated flexion of the tarsus and stifle during protraction, followed by sudden extension to the weight-bearing phase of the stride.

There is atrophy of the gastrocnemius and cutaneous hypalgesia/anesthesia of the caudal metatarsal region and bulbs of the heels. The flexor reflex is tested by pinching the skin over the dorsal aspect of the MCP joint. The reflex is present but weaker than on the normal side.

DIAGNOSIS
The diagnosis of peripheral nerve injuries is normally made by careful observation of clinical signs, including testing of reflexes and cutaneous sensation. It may not be possible to discern the effects of nerve damage until fractures are stabilized and soft tissue swelling subsides. The examination must carefully document the location and severity of
weakness, atrophy, and sensory and reflex alterations. The findings should be documented thoroughly and recorded at each examination so that progression can be determined.

Beginning 2 to 4 weeks after injury, progressive atrophy becomes apparent in large muscles supplied by the damaged nerve. Beginning about 2 weeks after injury, the distribution of muscular denervation can be determined objectively by needle electromyography in the sedated or anesthetized patient. This is particularly helpful in cases of apparent suprascapular or radial neuropathy to determine whether there is singular involvement of a particular peripheral nerve or injury at the level of the brachial plexus.

Nerve stimulation can be used to assess location, severity, and recovery from nerve injury. With both neurapraxia and axonotmesis, nerve conduction across the lesion is affected. Thus, when the proximal segment of the motor nerve is stimulated electrically, the amplitude of the evoked muscle action potential is reduced in proportion to the severity of the injury. It is technically possible to distinguish signs of neurapraxia from those that are the result of physical interruption of the axons of the nerve. Because axonal injury leads to degeneration of the distal nerve segment, electrical stimulation of the nerve distal to the injury site fails to evoke motor action potentials, or they are of reduced amplitude, when tested at least 9 days after the injury. In contrast, nerves blocked by neurapraxia evoke normal muscle responses after stimulation. It must be remembered that an injured nerve frequently has a mixture of neurapractic and axonotmetic lesions, and the findings may not clearly distinguish between the two types of injury. Sensory nerve conduction studies are performed in humans by electrically stimulating peripheral sensory axons at one point and recording sensory nerve action potentials at a more proximal point. This technique is useful for distinguishing lesions of the dorsal root from those involving peripheral parts of the nerve.

Nerve conduction procedures are not well established in the horse but “proof-of-principle” studies have been published for selected nerves in normal horses. High-resolution ultrasonography or magnetic resonance imaging may be used to help pinpoint the location of peripheral nerves and aid in precise stimulation and recording.

MANAGEMENT
Nonsurgical Management
The objectives of medical treatment of peripheral nerve injury are (1) reduction of swelling and inflammation at the site of injury, (2) support and stabilization of the denervated area, and (3) maintenance of the general health of the animal. In the case of lacerating trauma, the general principles of wound management apply. The wound should be cleaned, irrigated, debrided, and dressed and ventral drainage established. If severed nerve ends are visible, they can be tagged for later identification. Medical therapy for inflammation and swelling should be initiated, especially if there is obvious tissue swelling. This may include any combination of a cyclooxygenase inhibitor (e.g., flunixin meglumine, 1.1 mg/kg IV, IM, or PO once or twice daily), dimethyl sulfoxide (DMSO) (1 g/kg as a 10% solution IV or by nasogastric tube once or twice daily), and a glucocorticoid (e.g., dexamethasone, 0.05 mg/kg IV or IM once daily, or 0.1 mg/kg PO once daily). Additional anti-inflammatory effect can be provided by cold water hydrotherapy or local application of skin-permeant drugs such as DMSO or diclofenac. If there is an open wound or other risk for bacterial infection, broad-spectrum antimicrobial therapy should be initiated. This can be directed by culture results, if available.

Fractured or dislocated bones that have the potential to further injure nerves must be reduced and stabilized. Stall rest is essential to prevent further injury. In the case of paralyzed limbs, a protective wrap may be necessary to prevent damage caused by dragging or improperly placing the limb. A support wrap or light cast should be maintained on a leg affected with radial paralysis so as to prevent limb contracture. A support wrap should also be placed on the opposite limb to protect against breakdown caused by increased weightbearing. If the horse has difficulty alternating between recumbency and standing, it should be supported as necessary in an abdominal sling until it is able to rise unassisted. Because of the buoyancy provided by water, horses may be able to exercise affected limbs in swimming pools. Skin over bony prominences should be padded to prevent decubital injury; such injuries must be treated aggressively if they occur.

In foals, passive range-of-motion exercises should be performed on paralyzed limbs in an attempt to preserve joint flexibility and prevent contracture. Faradic or galvanic electrical muscle stimulation has been advocated for denervated muscle to help preserve muscle mass, and units designed for use in horses are available. This practice is controversial, however, and may possibly delay nerve regrowth into muscle. Hyperbaric oxygen is an approved adjunctive treatment for acute traumatic ischemic reperfusion injury of humans and theoretically could help horses with post-recumbency neuropathies.

Surgical Management
Because neurosurgery in horses is at a rudimentary stage, it is difficult to provide precise rules for assessment and intervention after mechanical nerve injury. The following guidelines are based on comparable situations in human medicine.

- In clean lacerating injuries in which the nerve ends are visible or when clinical examination reveals obvious motor and sensory deficits resulting from the injury at the laceration, primary repair may be indicated. In general, results of primary repair (within 3 to 4 days) are better than results of secondary repair (after 2 to 3 weeks).
- In nerve transections resulting from blunt lacerating trauma, secondary repair has a better surgical result. This allows time for control of infection and resolution of soft tissue swelling.
- Injuries that do not demonstrate evidence of early spontaneous recovery should be explored surgically. This applies especially to traumatic injury of the suprascapular nerve or injection injury of the sciatic nerve. Empirically, the outer time limit for exploration can be estimated from the observations that muscle must be reinnervated within 12 months and that nerve regrows at the rate of 1 inch per month. According to these precepts, the length in inches
from the injury site to the muscle supplied plus the time in months since the injury should not exceed 12. For example, if the peroneal nerve were injured 6 inches from its entry into the anterior tibial muscle, no more than 6 months should be allowed for spontaneous recovery of innervation.

Anastomosis

If the nerve is ruptured or severed, the retracted ends should be identified. With the help of an operating microscope, the damaged portions of the nerve should be trimmed and the proximal and distal stumps aligned as accurately as possible by epineurial repair. Coaptation is achieved by simple-interrupted epineurial sutures (8-0 to 10-0 monofilament nylon or silk) around the circumference of the anastomosis. A perfect superficial alignment can be achieved using epineurial vessels as landmarks, but the internal orientation of fascicular bundles and individual fascicles may not be correct (Fig. 54-3). The more technically difficult fascicular repair technique involves alignment and attachment of individual fascicular groups. Epineurial tissue is resected from around the circumference of the nerve, and fascicular groups are subsequently coapted with single sutures in the perineurium or connective tissue surrounding groups of fascicles. Nonsuture methods have been described and include wrapping the nerve, gluing the ends together with plasma clot or fibrin glue, or using a carbon dioxide laser to weld the nerve ends together.

Tension at the anastomosis site must be minimized by mobilization of the nerve ends and postoperative immobilization and rest. If the gap between the ends is too large to permit anastomosis without tension, a conduit technique may be considered, wherein the defect is bridged in such a way as to support axonal growth toward the distal nerve segment. For this purpose, either a tube or a graft is used. Silicone tubes, freeze-thawed muscle tubes, and collagen-based nerve gap conduits have been used. Nerve autographs

\[ \text{Figure 54-3. End-to-end repair of peripheral nerves. A, Epineural suture. Coaptation is achieved by single sutures in the epineurium around the circumference of the nerve. B, Group fascicular suture. Epineurial tissue has been resected, and fascicular groups are coapted with single sutures in the perineurium or connective tissue surrounding groups of fascicles. C, Tubular repair. (Modified from Lundborg GA: 25-year perspective of peripheral nerve surgery: Evolving neuroscientific concepts and clinical significance, J Hand Surg Am 2000;25:391.)} \]
from a remote donor site (e.g., sural nerve) also could be used for bridging a long nerve gap. In nerve injuries in which the proximal segment cannot be used for grafting, the distal segment theoretically can be implanted in end-to-side fashion into an epineurial window on an adjacent uninjured nerve. Similarly, the technique of direct neurotization of muscle has been validated experimentally in settings where nerve has been traumatically avulsed from muscle. A similar technique has been used in horses with left laryngeal hemiplegia. In this technique, a narrow strip of muscle with an intact nerve supply (the neuromuscular pedicle graft) is removed from the omohyoid muscle and inserted into the paralyzed dorsal cricoarytenoid muscle. Over the subsequent months, the dorsal cricoarytenoid muscle becomes reinnervated and is stimulated to contract during exercise.

After surgical exploration of a nonregenerating nerve, the damaged section can be removed and the ends anastomosed using one of the techniques described earlier.

**Neurolysis**

*External neurolysis* refers to the dissection of the nerve from a bed of scar tissue. This is indicated if there is obvious compression from fibrous tissue, and it is performed routinely in horses with suprascapular neuropathy. This procedure is described in Chapter 98. *Internal neurolysis* involves an incision of the epineurium and resection of scar tissue from between nerve fascicles.

**COMPLICATIONS**

In response to trophic factors produced at the site of nerve injury, misdirected axonal sprouting and Schwann cell proliferation may produce bulblike *neuromas*, either at the proximal stump of a transected nerve (end-neuroma) or within a partially disrupted nerve (neuroma-in-continuity). End-neuromas are a common complication of palmar digital neurectomy in horses suffering from navicular syndrome. Neuroma-in-continuity or fibrous entrapment at the site of injury or surgical repair is associated with a variety of pain syndromes in humans. The local sensitivity and reaction to touch that occur are described as dysesthesia (unpleasant abnormal sensation, whether spontaneous or evoked), allodynia (pain as a result of a stimulus that does not normally provoke pain), or hyperpathia (excessive reaction to painful stimuli). Disruption of sensory, motor, and autonomic fibers together can result in causalgia syndromes with sustained burning pain, vasomotor and sudomotor dysfunction, and later trophic changes of the skin. On the basis of the documented painful local effect of neuromas after palmar digital neurectomy, it is likely that similar syndromes occur in horses.

In attempts to reduce neuroma formation in nerves, the proximal stump has been exposed to CO2 laser energy or injected with doxorubicin. Neuroma treatment in humans generally involves excision of the neuroma and proximal translocation of the nerve stump into adjacent fat or into a burr hole created in bone.

In addition to permanent degenerative changes in muscle, fibrous replacement and contracture may result in reduced range of motion and permanent flexion of involved joints. Such an outcome is particularly likely after radial paralysis in the horse. Proper management by prolonged stall rest, orthotic support, and passive range-of-motion exercises may help prevent such an outcome. The use of electrical stimulation of muscle is controversial. Recent studies have indicated that the function of denervated muscle can be preserved only if use-specific stimulation paradigms are developed.

**REFERENCES**

Ocular surgery, unlike general surgery, often requires microsurgical instrumentation and techniques. Anesthesia must provide immobility of the eye. Additionally, the potential loss of vision because of ocular inflammation that occurs after most ocular procedures makes it essential that preoperative and postoperative pharmacologic control of inflammation be used.

**PHARMACOLOGIC PREPARATION**

Various drugs are used routinely before surgery on the eye, although corneal and intraocular procedures require more vigorous therapy.

**Antibiotics**

Antibiotics are used topically for 24 to 48 hours prior to intraocular procedures to sterilize the cornea and conjunctiva, which cannot be scrubbed. In view of the normal bacterial flora of the horse, a suitable antibiotic combination for preoperative topical use is neomycin sulfate, polymyxin B sulfate, and gramicidin (Neomycin, Burroughs Wellcome Company, Raleigh, NC) applied three or four times a day.

When corneal infection is suspected, a culture and sensitivity of the corneal lesion should be performed before or at the time of surgery. Because there is a shift from gram-positive to gram-negative organisms in many cases of conjunctivitis or keratitis, antibiotics such as gentamicin, tobramycin, and amikacin may be more appropriate. Fortified antibiotic solutions are indicated perioperatively in cases of severe or chronic nontreating deep ulcerative keratitis (Box 55-1). Ciprofloxacin (Ciloxan, Alcon Laboratories Inc, Fort Worth, Tex) and ofloxacin (Ocufluox, Allergan Pharmaceuticals Inc, Irvine, Calif), although not licensed for use in horses, have occasionally been used for severe and resistant bacterial infections. These drugs have a fairly broad antibacterial spectrum and may penetrate well into the eye. Postoperative endophthalmitis has been reported as a complication of intraocular surgery in the horse and warrants perioperative antibiotic therapy. Despite this precaution, postoperative bacterial infections may still occur. Interestingly, despite the prevalence of fungal organisms in the conjunctival sac of the horse, fungal endophthalmitis associated with surgery appears to be rare.

Systemic antibiotics are rarely needed for nonperforating corneal procedures. For intraocular surgery, systemic antibiotics are indicated. Procaine penicillin G and trimethoprim/sulfamethoxazole are reasonable choices when ocular inflammation exists or is caused surgically, because these drugs cross the blood–aqueous barrier in reasonable concentrations. The author often uses systemic doxycycline prior to intraocular surgery in horses.

**Anti-inflammatory Drugs**

Topical corticosteroids are indicated prior to intraocular surgery to control uveitis, unless corneal ulceration is a complicating factor (e.g., corneal or conjunctival surgery for therapy of corneal ulceration). Recommended preparations are dexamethasone 0.1% suspension (Maxidex, Alcon Laboratories) or prednisolone acetate 1.0% (EconoPred Plus, Alcon Laboratories) TID or QID.

Drugs that inhibit the cyclo-oxygenase (COX) pathway of arachidonic acid metabolism are beneficial in limiting inflammation during and after ocular surgery. Experiences in other species suggest that prostaglandins are involved in the breakdown of the blood–aqueous barrier and cause miosis in the surgically traumatized eye. Flunixin meglumine (Banamine, Schering Corporation, Kenilworth, NJ) administered intravenously (IV) or per os (PO) (1.0 mg/kg) is particularly effective in limiting ocular inflammation. Phenylbutazone, 2 g/kg PO once a day, may be used for a longer term than flunixin meglumine, but clinically it does not have as potent an anti-inflammatory effect on ocular tissues. Flunixin meglumine is ideal for an acute, perioperative anti-inflammatory effect in equine ocular surgery. Flurbiprofen (0.03%) (Ocufen, Allergan Pharmaceuticals; not licensed for use in the horse) is very effective in maintaining mydriasis during intraocular surgery, and in limiting ocular inflammation after surgery. Other COX-inhibiting NSAIDs—diclofenac Na (Voltaren, Novartis, New York, NY) and ketorolac (Acular, Allergan Pharmaceuticals)—are available in the United States or Europe. One to two drops are applied to the cornea four times a day or administered via subpalpebral lavage. These drugs may slow corneal epithelialization and limit corneal neovascularization, and they should be used with caution in cases of deep corneal ulceration, in which vascularization of the cornea is required for healing.

**Mydriatics**

Mydriatics are required to limit miosis and development of posterior synechia in inflamed eyes. Atropine sulfate
(Isopto Atropine, Alcon Laboratories) 1% is adequate when applied topically four times a day. In adult horses, when ocular inflammation is severe, 3% can be used, although care should be taken not to administer an overdose of this drug to avoid systemic absorption, which may lead to development of gastrointestinal stasis. In general, 1% atropine is most commonly used in horses and should be used to effect—that is, use as little as needed to achieve mydriasis. Sympathomimetics including Neo-

Sympathomimetics including Neo-

BOX 55-1. Preparation of Fortified Antibiotic Eyedrops

**PENICILLIN G**
1. Remove 5 mL "tears" from a 15-mL tear-substitute squeeze bottle.
2. Add 5 mL "tears" to 1 vial penicillin G (5 million U).
3. Replace 5 mL reconstituted penicillin into tear squeeze bottle (10 mL + 5 mL = 15 mL).
4. Final concentration of penicillin = 333,000 U/mL.

**OXACILLIN**
1. Remove 7 mL "tears" from a 15-mL tear-substitute squeeze bottle.
2. Add 7 mL tears to 1 ampule oxacillin (1 g).
3. Replace 7.2 mL reconstituted oxacillin into tear squeeze bottle (8 mL + 7.2 mL = 15.2 mL).
4. Final concentration of oxacillin, 66 mg/mL.

**CARBENICILLIN**
1. Reconstitute 1 vial carbenicillin (1 g) with 9.5 mL sterile water.
2. Add 1 mL reconstituted carbenicillin into 15-mL tear-substitute squeeze bottle.
3. Final concentration of carbenicillin, 6.2 mg/mL.

**TICARCILLIN**
1. Reconstitute 1 vial ticarcillin (1 g) with 10 mL sterile water.
2. Add 1 mL reconstituted ticarcillin into 15-mL tear-substitute squeeze bottle.
3. Final concentration of ticarcillin, 6.3 mg/mL.

**CEPHALORIDINE**
1. Remove 2 mL "tears" from a 15-mL tear-substitute squeeze bottle and discard.
2. Add 2 mL sterile saline to 1 ampule cephaloridine (500 mg).
3. Replace 2.4 mL reconstituted cephaloridine into tear squeeze bottle (13 mL + 2.4 mL = 15.4 mL).
4. Final concentration of cephaloridine, 32 mg/mL.

**CEFAZOLIN**
1. Remove 2 mL "tears" from a 15-mL tear-substitute squeeze bottle and discard.
2. Add 2 mL sterile saline to ampule cefazolin (500 mg).
3. Replace 2 mL reconstituted cefazolin into tear squeeze bottle (13 mL + 2 mL = 15 mL).
4. Final concentration of cefazolin, 33 mg/mL.

**VANCOMYCIN**
1. Remove 9 mL "tears" from a 15-mL tear-substitute squeeze bottle and discard.
2. Add 10 mL sterile water to 1 vial vancomycin (500 mg).
3. Replace 10.2 mL of reconstituted vancomycin into tear-substitute squeeze bottle.
4. Final concentration of vancomycin, 31 mg/mL.

**GENTAMICIN**
1. Add 2 mL parenteral gentamicin to the 5-mL dropper bottle of commercial ophthalmic gentamicin.
2. Final concentration of gentamicin, 15 mg/mL.

**TOBRAMYCIN**
1. Remove 2 mL "tears" from a 15-mL tear-substitute squeeze bottle and discard.
2. Add 2 mL parenteral tobramycin (80 mg) to tear-substitute squeeze bottle (13 mL + 2 mL = 15 mL).
3. Final concentration of tobramycin, 5 mg/mL.

**AMIKACIN**
1. Remove 2 mL "tears" from a 15-mL tear-substitute squeeze bottle and discard.
2. Add 2 mL parenteral amikacin (100 mg) to tear-substitute squeeze bottle (13 mL + 2 mL = 15 mL).
3. Final concentration of amikacin, 6.7 mg/mL.

**BACITRACIN**
1. Remove 9 mL "tears" from a 15-mL tear-substitute squeeze bottle.
2. Add 3 mL tears to each of 3 commercial vials of bacitracin (50,000 IU each).
3. Replace 9.6 mL reconstituted bacitracin into tear squeeze bottle (9.6 mL + 6 mL = 15.6 mL).
4. Final concentration of bacitracin, 9600 IU/mL.

**NEOMYCIN**
1. Remove 2 mL "tears" from a 15-mL tear-substitute squeeze bottle.
2. Add 2 mL tears to 1 vial neomycin (500 mg).
3. Replace 2 mL reconstituted neomycin into tear squeeze bottle (13 mL + 2 mL = 15 mL).
4. Final concentration of neomycin, 33 mg/mL.

**PIPERACILLIN**
1. Reconstitute 1 vial piperacillin (2 g) with 10 mL sterile water.
2. Add 1 mL reconstituted piperacillin into a 15-mL tear-substitute squeeze bottle.
3. Final concentration of piperacillin, 12.5 mg/mL.

painful spasms of the ciliary muscle. Atropine used for mydriasis achieves cycloplegia.

GENERAL ANESTHESIA

Routine and specific anesthetic procedures should be reviewed (see Chapters 19 to 22).

Of particular importance is maintaining anesthesia at a depth that adequately provides both ocular surface analgesia and ocular immobility. These objectives can be achieved in various ways without taking the animal to a potentially unsafe plane of general anesthesia. Topical anesthesia using proparacaine hydrochloride (Ophthaine, ER Squibb & Sons, Princeton, NJ) applied to the corneal and conjunctival surface reduces the requirement for deep general anesthesia when performing superficial corneal and conjunctival surgery.

For surgery involving deep corneal ulcers, in which traction on the globe could cause globe rupture, or for intraocular procedures, the use of muscle relaxants is recommended in any setting in which adequate intermittent positive-pressure ventilation and anesthetic monitoring are available. Muscle relaxants reduce ocular movement, including nystagmus, and by abolishing contraction of the extraocular muscles, they reduce pressure on the globe. This is especially important when performing cataract surgery in the horse to avoid collapse of the opened eye or vitreous prolapse.

Retrobulbar nerve blocks are occasionally used to avoid the need for systemic paralysis during intraocular surgery. Lidocaine 1% is injected into the retrobulbar space. Care must be taken to avoid the globe and the optic nerve. Inaccurate needle placement can have severe and even fatal consequences.

REGIONAL ANESTHESIA

Regional anesthesia may be required to perform an adequate ocular examination or to enable minor surgical procedures to be performed on the eye or eyelids. In particular, regional anesthesia is suitable for biopsy and for removal or cryotherapy of small eyelid or ocular neoplasms. Sedation is necessary prior to examining the eye. Xylazine (Rompun, 100 mg/mL, Mobay Corporation, Shawnee, Kan) administered at 0.4 mg/kg IV is suitable in most cases. If painful procedures are anticipated, butorphanol, 0.02 mg/kg IV (Torbugesic, Fort Dodge Laboratories, Inc, Fort Dodge, Iowa) can be used in conjunction with local nerve blocks. Detomidine hydrochloride (10 µg/mL), at a routine dose of 20 µg/kg IV (dependent on the patient the dosage may be selected from 10 to 40 µg/kg) (Dormosedan, Norden Laboratories, Lincoln, Neb) provides good sedation and analgesia for many minor ocular and periocular procedures in the horse. Anesthesia of the corneal and conjunctival surfaces must be achieved independently with topical proparacaine.

Sensory Nerves

The sensory innervation of the head in the periocular region is shown in Figure 55-1. The most frequently used sensory regional nerve block in the horse is the frontal nerve block, to anesthetize the central two thirds of the upper lid (Fig. 55-2). This block is needed when placing a subpalpebral lavage. The nerve is anesthetized either within or as it emerges from the supraorbital foramen, which can easily be palpated as a small depression approximately 2.5 cm (1 inch) above the free margin of the supraorbital process in an adult horse. A 25-gauge, 15-mm needle can often be inserted into the foramen (Fig. 55-3) and 1 to 2 mL Xylocaine can be injected. Care should be taken not to inject local anesthetic into the frontal artery or vein, which runs alongside the nerve.

The other nerves innervating the skin around the eye are the infratrochlear, lacrimal, and zygomatic nerves, which...
can be blocked as they cross the rim of the orbit (see Fig. 55-2). Anesthesia at these sites may be necessary for local excision of small tumors. In addition, local infiltration of 2% lidocaine may be used to augment these specific nerve blocks.

Motor Nerves
The most frequently anesthetized motor nerve is the auriculopalpebral nerve (see Fig. 55-2). The auriculopalpebral nerve innervates several of the periocular cutaneous muscles, particularly the orbicularis oculi muscle, which encircles the eyelids and is responsible for closure of the lids. To facilitate examination of a painful eye, especially one in danger of rupture because of a penetrating corneal laceration or a deep corneal ulcer, it is essential that the auriculopalpebral nerve be blocked. This nerve can be blocked at one of two sites (see Fig. 55-2): (1) in the depression where a line along the dorsal border of the zygomatic arch intersects with a vertical line drawn along the posterior border of the ramus of the mandible, or (2) at the palpebral nerve where it crosses the superior margin of the zygomatic arch, halfway between the eye and the ear (Fig. 55-4). At the latter site, the nerve can readily be palpated. Three to 6 mL of lidocaine hydrochloride 2% (Xylocaine, Astra Pharmaceutical Products, Westborough, Mass) is injected at either site. Anesthesia at the more posterior site occasionally results in temporary facial paralysis, with drooping of the lip on the injected side.

Local and general anesthesia may be combined to limit eye movement during surgery and to abolish the oculocardiac reflex. Retrobulbar anesthesia of the extraocular muscles can be used. A 7.5-cm (3-inch), 20-gauge needle is used to deposit 5 to 10 mL of lidocaine into the four quadrants of the orbit. The needle passes superiorly through the center of the upper lid and is directed parallel to the globe. Temporally, the needle passes through the lateral canthus skin and follows the globe posteriorly. Distally, the needle passes through the skin or bulbar conjunctiva posteriorly and nasally to avoid the optic nerve. Nasally, the needle passes through the base of the elevated third eyelid and posteriorly into the orbit. However, this technique should not be used when performing intraocular surgery or when repairing a defect in the cornea (laceration or ulcer), in which anesthetic injected into the orbit may put pressure on the globe. Use of a modified Peterson’s block has been reported in the horse, but it rarely has an application in ocular surgery.

SURGICAL PROCEDURE

Positioning
For most ophthalmic procedures, the horse should be positioned in lateral recumbency, with the nose tilted upward so that the palpebral fissure is as near to horizontal as possible. This can usually be achieved with the help of sandbags. Space should be available adjacent to the animal for the surgeon to sit comfortably and position the operating microscope, if it is used. The surgeon’s arms should be supported either by an arm rest attached to an adjustable stool or by the patient’s head.

Surgical Site Preparation
The periocular area should be clipped and cleaned with three applications of povidone-iodine solution (Betadine solution, Purdue Frederick Company, Norwalk, Conn) diluted to 50% with sterile saline. This diluted povidone-iodine solution is also applied to the clipped eyelid margins and conjunctival cul-de-sac. Before intraocular surgery, the author uses three applications to the conjunctival sac and around the eyelids of sterile 5% povidone-iodine solution (Alcon Laboratories) The area is rinsed with sterile physiologic saline or a sterile ophthalmic irrigating solution (Dacriose, IOLAB, Claremont, Calif).
Draping
Cotton or paper quarter drapes are applied around the eye, and a fenestrated, disposable, plastic-coated paper drape (Convertors Eye Sheet, no. 8441, Baxter Healthcare Corporation, Deerfield, Ill) of a size large enough to cover at least the head and neck is applied over the quarter drapes. Finally, a disposable plastic barrier drape (Steri-Drape Surgical Drape, 3M Corporation, St. Paul, Minn), with an ellipse cut out the size of the eye, is applied over the other drapes and periocular exposed skin.

Illumination
For adnexal surgery, regular operating room lights are suitable. For corneal, conjunctival, and intraocular surgery, either a head-mounted focal light source or coaxial lighting built into the operating microscope is essential to reduce reflections from the eye.

Magnification
For all microsurgical procedures, an operating microscope is recommended. For eyelid and conjunctival surgery, a powerful magnifying loupe with 2 to 4 times magnification and a focal length of 20 to 30 cm is needed.

Instrumentation
Particular attention should be paid to the quality of the instruments purchased for ophthalmic microsurgery. In this specialty, it is false economy to use cheap instrumentation. Ophthalmic instruments are designed to be held with the fingers, with movements accomplished by the fingers and wrist and with the lower arm supported at the elbow.

Two forceps are recommended for routine use. A straight tissue forceps with teeth (e.g., Bishop-Harmon forceps) is suitable for handling the lids and episcleral fascia. A fine forceps with teeth (e.g., Castroviejo or Troutman-Barraquer corneal utility forceps) is needed for handling the conjunctiva or cornea. Iris forceps may occasionally be required for intraocular surgery (Fig. 55-5).

Scissors used for ocular procedures include the Stevens tenotomy scissor, the wide flat blades and rounded tips of which are ideal for conjunctival dissection. The Castroviejo corneal section scissors (left and right) are required for cutting corneal tissue; in the horse, as in other species, the corneal thickness requires initial outlining of the corneal incision with a scalpel. Bard-Parker scalpels and handles are suitable for many ophthalmic surgeries, especially for the adnexa, in the horse (see Chapter 12). Additionally, for corneal and intraocular surgery, the more delicate Beaver scalpel handle and blades (R. Beaver, Inc., Waltham, Mass) are recommended. In particular, Beaver blades nos. 75, 64, and 6900 may be useful (see Fig. 55-5).

Two sizes of needle holders are required for ocular surgery. The Alabama-Green needle holder or its equivalent is suitable for needle sizes used in the eyelids. For suturing conjunctival and corneal areas, a fine straight or curved holder, such as the Barraquer or Castroviejo needle holder, is recommended (see Fig. 55-5).

Ophthalmic instruments should be stored in a tray that keeps instruments separated on felt or rubber mats or in
polyester foam compartments. Tips of forceps, scissors, and needle holders should be protected when not in use.

Instruments should be cleaned very carefully with fine brushes. To avoid corrosion, never autoclave ophthalmic microsurgical instruments, particularly scissors. Air-dry instruments and, if possible, use ethylene oxide gas for all instrument sterilization. Hot-air, dry-heat sterilization at 160° C (320° F) for 4 hours, or 180° C (356° F) for 2 hours is adequate.15

Suture Materials

Both nonabsorbable and absorbable suture materials are used in ophthalmic surgery. Nonabsorbable materials that may be used are silk 4-0 to 6-0 for eyelid procedures, 8-0 for scleral incisions, nylon 7-0 to 8-0 for corneal sutures, and nylon or polypropylene monofilament 4-0 to 6-0 for eyelid procedures.

Absorbable suture materials are most often used for conjunctival or corneal surgery. In particular, polyglycolic acid (Dexon, Davis and Geck; GE-3, Ethicon), micropoint reverse-cutting needles for sclera and conjunctiva (G-1, Ethicon), and micropoint spatula needles (TG-140-8, Ethicon) for corneal sutures. (Additional information on suture materials and needles can be found in Chapter 17.)

Needles

A reasonable selection of suture needles for ocular surgery are reverse-cutting needles for most eyelid procedures (CE-2, Davis and Geck; GE-3, Ethicon), micropoint reverse-cutting needles for sclera and conjunctiva (G-1, Ethicon), and micropoint spatula needles (TG-140-8, Ethicon) for corneal sutures. For corneal suturation, 9-0 monofilament material is suitable.

Supplemental Equipment

Additional equipment that may be required are cellulose sponges (Weck Cel Surgical Spears, Edward Weck and Company, Inc, Raleigh, NC), ocular and intraocular irrigating solution (B.S.S., Alcon Laboratories, Surgical Products Division), and cautery. Regular cautery units may be needed for eyelid procedures. Fine-tip disposable cautery units are ideal for microsurgical application (Disposable cautery no. 6821 Fine Tip, Edward Weck and Company).

Cryotherapy units used in general surgery are appropriate for ophthalmic work. Liquid nitrogen, nitrous oxide, or carbon dioxide cryotherapy units are used for tumor therapy in the horse.

Butylcyanoacrylate tissue adhesive (Ophthalmic Nexaband, CRX Medical, Raleigh, NC) may be used in the treatment of various types of corneal ulcer.

Various substances have been used in horses for the support of deeper corneal ulcers—usually some form of collagen matrix. These include porcine small intestinal submucosa (Vet Biosist, Global Veterinary Products Inc. New Buffalo, Mich),16 porcine urinary bladder (Corneal Discs and Lyophilized Sheets, ACell Vet Inc, Jessup, Md) bovine endocardium and dura mater (Dura Guard, Synovis Surgical Innovations, St. Paul, Minn). These vary in their thickness and the degree of support that they provide.

Contact lenses may be used to promote healing of indolent corneal ulcers in the horse. Various sizes are available (OcularVision, Buellton, Calif).17,18

Viscoelastic substances including sodium hyaluronate (Healon, Pharmacia Ophthalmics, Pasadena, Calif; AmVisc, IOLAB Corporation), sodium chondroitin sulfate–sodium hyaluronate (Viscoat, Cooper Vision, Bellevue, Wash), and hydroxypropyl methylcellulose (Occucoat, Storz Pharmaceuticals, St. Louis, Mo) may be used to protect the corneal endothelium during intraocular surgery and may help maintain the anterior chamber if a sufficient volume is used.19

Surgical equipment that is finding applications in equine ophthalmic surgery includes the carbon dioxide laser, the Nd:YAG laser (Surgical Laser Technologies, Malvern, Pa) and the diode laser (DioVet, Iris Medical, Mountain View, Calif). Laser therapy has been used in horses for treatment of iris cysts20 and glaucoma and may be a better therapeutic approach to glaucoma in this species in view of the poor response to medical therapy.21 The approach to cyclophotocoagulation with the Nd:YAG or diode laser has been recently reviewed.22 Laser sites for diode laser cyclophotocoagulation have been described for the horse.23
Exposure
Adequate exposure is achieved by using an eyelid speculum. In many cases, a simple large wire speculum of the Barraquer type is adequate. A Guyton-Park eyelid speculum may provide better exposure in adult horses.

Fixation of the globe for conjunctival, corneal, and intraocular surgery may require the use of stay sutures (4-0 silk, reverse-cutting needle) inserted into the perilimbal episcleral fascia. Sutures may be tagged and attached to the adjacent drape for fixation.

APPLICATION OF MEDICATIONS
Medications can be applied in liquid or ointment formulations. Application of solutions and suspensions to the equine eye from a dropper bottle is extremely difficult, especially if this is to be carried out by the owner. Use of ointment tubes carries the risk of inadvertent corneal injury. These problems are compounded in a horse with a painful eye either before or after surgery.

Subpalpebral Lavage
Use of a subpalpebral lavage is the most satisfactory solution to the problem of ocular medicine application in the horse, enabling delivery of adequate medication over an extended period of time with minimal risk to horse or owner. The technique described here has been found to be most reliable.

To place a subpalpebral lavage tube, the horse must be sedated with xylazine or detomidine hydrochloride. Xylazine may be supplemented with butorphanol tartrate for analgesia. Despite these measures, a twitch may be needed. The auriculopalpebral and frontal nerves should be anesthetized. Additionally, a small bleb of 1 mL of 2% Xylocaine should be applied at two sites in the upper lid at which the lavage placement needles will penetrate the skin.

Proparacaine hydrochloride is squirted under the upper lid into the conjunctival fornix using a 1-mL syringe and the hub (the needle broken off) of a 25-gauge needle.

The lavage can be performed in various ways: The simplest approach is to place a lavage tube with a soft footplate into the upper lateral or medial conjunctival fornix, well away from the corneal surface (Fig. 55-6). The author has used a commercially available subpalpebral eye lavage kit, supplied complete with 12-gauge needle, Silastic tubing, and silicone footplate (Mila International, Inc, Erlanger, Ky) (Fig. 55-7).

Others have used an inferomedial placement of the lavage tubing with a homemade footplate that resides in the space between the lower palpebral conjunctiva and the anterior surface of the third eyelid. This placement may reduce the incidence of corneal damage from the lavage tubing.

For upper lid placement, the upper lid is grasped centrally and elevated away from the globe. A 7- to 8-mm, 12-gauge needle, detached from the hub, is directed laterally or medially up into the recess of the upper conjunctival fornix as far as possible. The needle is advanced through the full thickness of the lid, emerging laterally above the upper eyelid, near the rim of the orbit (which can be felt with the needle) (Fig. 55-8). A piece of folded gauze sponge helps grasp the needle as it is pushed through the tough lid skin. An assistant can apply counterpressure with the opened ends of a needle holder, over the tented area of the lid where the needle will emerge. Keeping the needle away from the cornea, Silastic tubing (Dow Corning Silastic Medical-Grade Tubing, cat. no. 602-175; 0.030-inch ID by 0.065-inch OD) is passed through the needle from the blunt to the pointed end (see Fig. 55-8). When the tubing emerges from the point of the needle, the needle and tubing are pulled through the lid using needle holders to grasp the needle. Silastic tubing is preferable to polyethylene tubing because the latter is less pliable and more likely to irritate the cornea. The footplate is seated as far dorsally in the conjunctival fornix as possible.

If only Silastic tubing is available and no footplate is attached, a loop of tubing can be seated in the conjunctival fornix. The procedure is essentially identical to that just described for the lateral penetration of the tube into the conjunctival fornix. Once the tubing is placed in the upper lateral part of the lid, the procedure is repeated medially. The entry (lateral) and exit (medial) holes should be placed...
4 to 5 cm apart, and the tubing should enter and emerge from the respective holes at an angle to prevent the tubing inside the lid from hanging down and rubbing the cornea (Fig. 55-9). The end of the Silastic tubing that emerges medially is tied on itself several times to prevent the tube from slipping out (Fig. 55-10). The end with the knot is pulled out from the eyelid, and the tube is laid back over the eyelid skin with the knot adjacent to the lateral insertion hole (Fig. 55-11). The middle point of the tube in the conjunctival sac can then be judged, and three to five holes are placed in the Silastic tube close together at the center of the conjunctival portion of the tubing using a 23-gauge needle (Figs. 55-12 and 55-13). Wide spacing of these holes along the tube may result in subcutaneous leakage of medications, which may cause tissue reactions. The tubing is subsequently repositioned. A piece of waterproof white tape is attached to the tubing adjacent to the lateral exit hole and halfway between the eye and the poll. The tape may be sutured to the head skin with nonabsorbable monofilament sutures using a regular cutting needle, although this is not essential (Fig. 55-14). The Silastic tubing runs through the braided forelock and along the base of braids in the mane to the withers, or from the mane behind the ears onto a halter (see Fig. 55-14). A feline indwelling catheter (20-gauge, with 22-gauge needle, Sherwood Medical, Ireland) is inserted

**Figure 55-8.** Silastic tubing is threaded through the needle.

**Figure 55-9.** The needle is placed high enough in the fornix to avoid corneal irritation from the Silastic tubing.

**Figure 55-10.** A knot is tied consisting of two half-hitches adjacent to its medial exit from the eyelid.

**Figure 55-11.** The medial end is pulled from the fornix and laid back over the lid to the lateral needle hole to assess the central point of the tube.
1 cm into the free end of the Silastic tubing, and the catheter is attached to a tongue depressor with tape. An injection cap is applied to the catheter. The tongue depressor and catheter can be taped either to the halter or to the mane at the withers (see Fig. 55-14).

Medications can be injected through the remote catheter and flushed to the eye with 1 to 2 mL of air. Alternatively, if several medications are to be used and there are no incompatibilities between them, they can be used sequentially in the tubing and the tubing always kept primed with medication, or all of the medications can be mixed in one bottle in the appropriate concentrations. Subconjunctivally implanted micro-osmotic pumps have been successfully evaluated for continuous release of medications into the conjunctival sac in the horse and may provide a reasonable alternative to a subpalpebral lavage in some cases.25

Subconjunctival Injections

Subconjunctival injections are useful when the horse can be medicated only infrequently. With adequate sedation, an auriculopalpebral block, and topical proparacaine anesthesia, a 25-gauge needle is advanced beneath the bulbar conjunctiva a few millimeters behind the limbus, where the drug is injected. The drug should not be injected beneath the palpebral conjunctiva because it will be rapidly absorbed systemically with minimal benefit to the eye itself.

All horses in which a lavage system is installed should be given a tetanus toxoid booster. The tubing should be placed high enough in the cul-de-sac of the upper eyelid to avoid rubbing the cornea. Loosening of the lateral pieces of tape should be noted immediately and the tape replaced if needed. If the openings of the tubing move from the conjunctival sac into the subcutaneous tissue, medications may be deposited at this site, resulting in considerable reaction and swelling. If this occurs, medications should be discontinued by lavage and systemic antibiotics and nonsteroidal anti-inflammatory drugs administered for 24 to 48 hours until the swelling subsides. The tubing should be adjusted to ensure that the medications discharge only into the conjunctival sac.

Occasionally, a horse breaks the tubing somewhere on the head. If this happens, a new tube can be joined to the old piece remaining in the upper lid with 2 to 3 cm of a Tomcat catheter and the new tube pulled through the lid, laterally to medially, and reattached. Neck cradles may help prevent this problem. When placement of a lavage system in the upper lid is for any reason impractical, the same technique can be used in the lower eyelid after the appropriate sensory and motor nerves are blocked.

Other techniques have been described to apply medications to the equine eye. A size 8 French 105-cm infant feeding tube may be passed up the nasolacrimal duct and used to deliver medications to the eye.26

Figure 55-12. Several holes are made in the central area of the tube with a 23-gauge needle.

Figure 55-13. The needle holes should be closely clustered together in the conjunctival fornix to avoid subcutaneous leakage.

Figure 55-14. The lavage tubing is sutured to the head and attached to the halter or threaded through braids in the mane to the withers.
The antibiotics most commonly applied in this manner are amikacin (25 mg), gentamicin (25 to 50 mg), ampicillin (250 mg), cephalexin (100 mg), and penicillin G (500,000 IU). In eyes where difficulty is encountered maintaining mydriasis or cycloplegia, 15 mg (1 mL) of atropine (L.A. Injectable) can be used. Topical atropine solutions should not be injected subconjunctivally. For uveitis therapy, subconjunctival betamethasone acetate and betamethasone sodium phosphate (Betavet, Upjohn, Kalamazoo, Mich) application has proved successful. Methylprednisolone acetate, which is a long-acting drug, leaves subconjunctival plaques, potentially causing conjunctival irritation. Additionally, these drugs are contraindicated in eyes that postoperatively develop corneal ulcers or endophthalmitis. Most of these subconjunctival therapies should be repeated daily. Dosages of other drugs for subconjunctival injection have been listed elsewhere.27

AFTERCARE

Postoperative medication is usually similar to that initiated prior to surgery. During recovery from anesthesia, tear production and blinking may be reduced and topical petrolatum and mineral oil ointment (Lacrilube, Allergan Pharmaceuticals) should be applied to the corneal and conjunctival surfaces.

Dimethyl sulfoxide (Domoso 90%, Syntex Animal Health Inc, West Des Moines, Iowa) may be applied to the outside of the eyelids to reduce swelling after eyelid surgery, surgical placement of a silicone intraocular prosthesis, or enucleation.

If a horse attempts to rub the eye after surgery, the application of a neck cradle or cross-tying is an option. Often, these methods are not needed if adequate attention is paid to analgesia. Flunixin meglumine administered intravenously or in the feed may keep the horse comfortable after oculary surgery. Protective hoods are available in various sizes that cover the periocular area and prevent direct trauma to the eye (Veterinary Protective Hood, Equestrian Care Products, Leesburg, Fla.).

CHAPTER 56

Eyelids
Thomas R. Miller

ANATOMY

The eyelids should fit closely to the globe, with the exception of a recess medially that forms the lacrimal lake. A fleshy prominence, the lacrimal caruncle, is found at the medial canthus. The caruncle is frequently pigmented. The lacrimal puncta are small (2 mm), slit-like openings on the conjunctival surface adjacent to the eyelid margin, approximately 8 mm from the medial canthus on the upper and lower eyelids.

Distinct cilia (eyelashes) are present on the upper eyelid only, and they extend over the lateral two thirds of the eyelid. Vibrissae (tactile hairs) are present at the base of the upper eyelid medially, and along the base of the lower eyelid.

The eyelids consist of four major layers. From the external surface, they are skin, muscle, tarsal plate, and conjunctiva (Fig. 56-1). The skin, covered by fine hair, with small sebaceous and sweat glands, is thin and freely moveable, except adjacent to the eyelid margin, where it is firmly attached to the underlying tissue. The subcutaneous tissue consists of irregular connective tissue and is devoid of fat.

The subcutaneous connective tissue blends with the orbicularis oculi muscle, which is composed of striated muscle fibers interspersed with dense connective tissue. This tissue is continuous with the deep and intermediate orbital fascial sheaths.

Deep to the orbicularis oculi muscle are the tarsal or meibomian glands, surrounded by a plate of connective tissue. The tarsal plate is not as well developed in the horse as in humans. Tarsal glands resemble modified sebaceous glands and may be seen from the conjunctival surface as a palisade of yellow glands measuring 5 mm by 1 mm, oriented perpendicular to the eyelid margin. The ducts of the glands open on the eyelid margin. The tarsal glands produce the oily secretion that forms the superficial layer of the tear film, which provides tear stability.

There are additional glandular structures at the eyelid margins that are associated with the cilia. The apocrine glands (glands of Moll) and sebaceous glands (glands of Zeis) resemble the glands associated with all hair follicles. The inner surface of the eyelid is lined by conjunctiva, a two-layered tissue consisting of nonkeratinized stratified columnar epithelium interspersed with goblet cells, and the deeper substantia propria, a loose connective tissue layer.

Musculature and Motor Control

The orbicularis oculi muscle is a flat, elliptical muscle that surrounds the orbit and functions as a sphincter, acting to close the eyelids (Fig. 56-2). Attachments by the palpebral ligaments prevent a circular closure. The medial palpebral ligament is a defined fibrous band connecting the orbicularis oculi muscle with the lacrimal tubercle. The lateral palpebral ligament is less distinct, formed by decussating muscle fibers. The orbicularis oculi muscle is innervated by the palpebral branch of the facial nerve (cranial nerve [CN] VII).

Opening of the eyelid fissure is a function of several muscles, exerting a force perpendicular to that of the orbicularis oculi muscle. One is the levator palpebrae superioris muscle, which arises from the pterygoid crest and passes...
posterior to the orbicularis oculi muscle, ending before it reaches the eyelid margin. Innervation is provided through the dorsal branch of the oculomotor nerve (CN III). Another is Müller’s muscle, which is a smooth muscle closely associated with the levator palpebrae superioris muscle and is thought to be under sympathetic innervation.

The small levator anguli oculi medialis muscle also serves to raise the upper eyelid. Originating at the base of the zygomatic process, it spreads over the medial upper eyelid, blending with the orbicularis oculi muscle. The action of this muscle is responsible for the angle at the junction of the medial and middle third of the upper eyelid. It is innervated by the palpebral branch of the facial nerve (CN VII).

The frontalis muscle inserts laterally on the upper eyelid. It, too, is innervated by the palpebral nerve.

The malaris muscle originates from the rostral fascia of the lower eyelid, spreads as a thin muscle to insert on the ventral orbicularis oculi muscle, and functions to depress the lower eyelid. Innervation is provided by the dorsal buccal branch of the facial nerve.

The upper eyelid is the larger and more mobile section, and it therefore provides much of the blinking function.

Sensory Innervation of the Eyelids

The sensory innervation of both the upper and lower eyelids is provided by the ophthalmic and maxillary branches of the trigeminal nerve. The ophthalmic branch enters the orbit through the orbital fissure and divides into several branches—the frontal, lacrimal, and nasociliary nerves. The frontal branch passes rostrally through the periorbital fascia and exits the orbit through the supraorbital foramen. As the supraorbital nerve, it ramifies over the forehead and innervates much of the upper eyelid. The lacrimal nerve passes in association with the dorsal rectus and levator palpebrae superioris muscle to ramify in the lacrimal gland and the upper eyelid in the area of the lateral canthus. The nasociliary nerve gives rise to the infraorbital nerve, which passes under the dorsal rectus muscle to ramify medially, providing sensory innervation to the eyelids at the medial canthus, as well as to the lacrimal caruncle, third eyelid, nasolacrimal puncta and ducts, and areas of the conjunctiva.

The lower eyelid derives most of its innervation from the zygomatic nerve, a branch of the maxillary nerve, which ramifies temporally in conjunction with the lacrimal nerve to supply the lateral region of the lower eyelid. Anatomic landmarks and injection techniques for regional analgesia were discussed in Chapter 55.

Vascular Supply

Eyelids are extremely vascular, deriving blood supply from the facial, transverse facial, and supraorbital arteries and the malar branch of the infraorbital artery. These vessels anastomose fully, creating tarsal arterial arcs, which are located in the orbital septum superficial to the tarsus. Vessels arising from these arcs penetrate the tarsus to supply the palpebral conjunctiva. Blood vessels are located in both the deep and the superficial layers of the conjunctiva. As a result of this abundant vascularity, eyelids tend to bleed profusely during surgery.

Diagnostic Procedures

Clinical Examination

As in making any diagnosis, an accurate history, including information on the duration of the problem, changes in appearance, previous therapy, and response to therapy, is essential. It is important to perform a preliminary evaluation of the eyelids before the administration of sedatives, regional nerve blocks, or topical anesthesia. This evaluation permits an accurate assessment of conformation, eyelid function, and neurologic reflexes.

The size of the palpebral fissure should be evaluated. It may appear small in cases of microphthalmos, ankyloblepharon, symblepharon, or ptosis, or enlarged in cases of glaucoma or exophthalmos. The shape and position of the eyelid margin should be assessed for the presence of entropion or ectropion. The angulation of the upper eyelid should be assessed. Exaggerated notching may suggest decreased intraocular pressure; ptosis, or exophthalmos. The position of the eyelid may be evaluated by examining the angle of the cilia in relation to the globe.

Eyelids should move freely while fitting tightly to the globe. Movement may be restricted by the presence of blepharospasm, adhesions, neoplasia, blepharoedema, or neurologic deficits.

Neurologic function of the eyelids may be assessed in three ways—by the palpebral, the menace, and the corneal reflexes. The palpebral reflex is elicited by touching the eyelid or tactile hairs. The trigeminal nerve forms the afferent pathway. The facial nerve is the efferent pathway, causing a blink reflex. The corneal reflex is similar, except that the reflex is tested by touching the cornea with a wisp of cotton to elicit the blink response, thereby allowing assessment of corneal innervation rather than eyelid sensitivity. The menace response uses a visual stimulus to elicit a blink response. The retina and optic nerve start the afferent pathway, which continues through the lateral geniculate nucleus to the visual cortex. The efferent pathway starts in the visual cortex and travels to the cerebellum through the internal capsule and pontine nucleus and continues to the facial nucleus to activate the orbicularis oculi muscles.

After evaluation of neurologic and motor function of the eyelid, it may be necessary to sedate the horse or perform a palpebral nerve block to allow further examination. Eyelids should be palpated in a closed position to detect and define any swelling or presence of masses. Eyelid edema associated with circulatory stasis can be differentiated from inflammation, because edema is usually cool to the touch, whereas inflammatory swelling is warmer than normal and often painful. A more detailed inspection of lesions using magnification and focal illumination may be beneficial in some cases, such as in suspected ectopic cilia or conjunctival masses. This may be provided by a magnifying head-loupe and a transilluminator, or a hand-held slit-lamp biomicroscope.

Laboratory and Histopathologic Examination

Definitive diagnosis of eyelid lesions may be provided by cultures, exfoliative cytology, fine-needle aspiration, or biopsy and histopathology. The collection of samples may be facilitated by the use of sedation, a palpebral nerve block...
to immobilize the eyelids, or both. Any draining tract or penetrating wound should be cultured. In granulomatous or deep blepharitis, culture of excised tissue within the lesion may be preferable to simple swabbing. Cytology samples may be collected using a platinum Kimura spatula, cytology collection brushes, or, more simply, the butt-end of a Bard-Parker scalpel blade. Specimens should be spread on glass slides and air-dried. It is preferable to collect several slides to allow the preparation of a variety of staining techniques, such as the Gram stain, fungal stains, and appropriate cytology stains.

Excisional biopsy for histopathology requires analgesia provided by infiltration with a local anesthetic or by the appropriate regional nerve blocks (see Chapter 55). Excision of large lesions requiring extensive reconstruction is frequently performed with the horse under general anesthesia. This is also true for deep lesions or penetrating injuries that require surgical exploration. In such cases, survey radiographs or ultrasonography may be useful to localize the lesion and assist in identifying a foreign body. The injection of contrast material into fistulous tracts may also be useful in delineating the lesion.

**SURGICAL DISORDERS**

Congenital eyelid anomalies are relatively uncommon in horses. Disorders such as eyelid agenesis and dermoids (see Chapters 57 and 60) are rare but may require surgical correction when they are present. Ankyloblepharon (fusion of the eyelids) is abnormal in foals and may be corrected readily by applying digital traction on the eyelids. In difficult cases, a scissor blade can be inserted medially in the fissure, and advanced laterally by sliding, not cutting, to aid in eyelid separation.

Acquired eyelid disorders in the horse are frequent and arise as a result of neoplasia, trauma, or inflammatory disorders.

**Entropion**

Entropion is defined as an inward rolling of the eyelid, allowing facial hair to rub on the cornea. Irritation causes blepharospasm and excessive tearing. Keratitis and corneal ulcers are common sequelae. Entropion is more often seen in young foals and may be hereditary, or secondary to a variety of factors, such as blepharospasm, loss of eyelid turgor, and enophthalmia. Because many cases of entropion in foals are seen in dehydrated or septicemic patients, acquired entropion seems more likely. Therefore, surgical correction may not be indicated or desirable as primary therapy.

**Nonsurgical Management**

In acute cases, manual repositioning of the eyelids, repeated as required, combined with an ophthalmic ointment to lubricate and protect the cornea may be all that is required. Temporary eversion of the eyelid may be achieved by injection of procaine penicillin G into the eyelid. A 20-gauge, 2.5-cm (1-inch) needle is inserted into the lower eyelid above the ventral orbit. A 0.5 to 1 ml. bleb is injected at the base of the affected area, and massaged up to the eyelid margin. The resultant swelling persists for up to 48 hours and may alleviate the entropion. Injection of liquid paraffin has also been reported but is not recommended because of the risk of recurring inflammation.

**Surgical Management**

**EVERTING SUTURE**

An entropion that fails to respond to manual correction may be managed by the use of everting sutures (Fig. 56-3). Sutures should be placed in a vertical mattress pattern. Two or more sutures may be required, depending on the severity of the entropion. Correct placement of these sutures is essential for success. To ensure adequate eversion of the eyelid, the suture should be placed as close as practical to the eyelid margin (approximately 3 mm). Secondly, the span of the suture should not be so great as to produce overcorrection. The ectropion caused by this error may interfere with proper eyelid closure. Also, the increased tension may cause the suture to cut through the skin, leading to failure of the procedure and increased scar formation. Nonabsorbable suture material, such as monofilament nylon or silk (3-0 or 4-0) is preferred. Sutures are left in place for 7 to 10 days. This method is frequently adequate to correct the entropion permanently if predisposing factors are corrected.
RECONSTRUCTIVE TECHNIQUES

An acquired entropion in older horses is usually associated with cicatrix formation and requires permanent surgical correction. Horses with large areas of eyelid involvement are best treated using a modified Hotz-Celsius technique (Fig. 56-4). In this procedure, a crescent-shaped area of skin and orbicularis oculi muscle is removed. The initial incision is made close to the eyelid margin (3 mm). The width and length of the excised skin should be determined prior to induction of anesthesia. Incisions are made with a no. 15 scalpel blade. A Jaeger eyelid plate or sterile tongue depressor inserted into the conjunctival fornix stabilizes the skin and facilitates the excision. After the skin is incised, the skin and orbicularis oculi muscle are undermined and dissected free using scissors.

Closure is achieved with a single layer of simple-interrupted sutures using a fine (4-0) nonabsorbable suture material, such as silk or monofilament nylon. Sutures may be removed after 10 days.

When an entropion is associated with a localized eyelid lesion, such as a cicatrix, a Y-to-V repair may be the best surgical option (Fig. 56-5). The arms of the Y should extend slightly beyond the extent of the lesion. The height of the Y is determined by the degree of eversion required. The adjoining skin should be undermined. The underlying scar tissue should be dissected from the skin and orbicularis oculi and excised.

Ectropion

Ectropion represents an outward rolling of the eyelid, resulting in increased exposure of the globe or conjunctiva. In horses, it is frequently associated with cicatrix formation. Although a variety of surgical techniques have been described for correction of ectropion in dogs, the most useful technique in horses is the V-to-Y procedure (Fig. 56-6). As in entropion repair, the V should span the extent of the affected eyelid area, with enough height to release the tension creating the ectropion. The underlying cicatricial scar tissue should be excised.

Trichiasis

Abnormal cilia are rare in horses. Trichiasis, an eyelash or hair growing from a normal follicle directed onto the cornea, is the most common and is usually associated with cicatrix formation. The ideal treatment is appropriate
blepharoplasty to reconstruct the eyelid defect. An alternative procedure, such as electroepilation or cryoepilation, may be used to remove offending hairs.5 For cryoepilation, the cryoprobe should be centered at the base of the meibomian glands. Freezing should continue until the iceball extends beyond the gland openings on the eyelid margin. Permanent depigmentation may result.

Distichiasis
Distichiasis, a cilium arising from tarsal glands, and districchiasis, multiple cilia arising from a single follicle, are rare and may be removed by electroepilation or cryosurgery.

Eyelid Trauma
Because of the propensity of horses for tossing their head when frightened, eyelid trauma is common. Blepharoedema and hematomas occur readily because of the lack of dermal fatty tissue in the eyelid.5 Ice packs, dimethyl sulfoxide applied to the eyelid, and flunixin meglumine (Banamine, Schering, Kenilworth, NJ) (1 mg/kg IV) may reduce the severity of the lesion. If eyelid function is impaired, a third eyelid flap or temporary tarsorrhaphy may be necessary to protect the globe. If eyelid abrasions are present, topical antibiotic ointments are indicated. The globe should be examined carefully to rule out traumatic injury.

Eyelid lacerations should be thoroughly flushed with saline and explored to remove any foreign material. To improve the surgical results, longstanding infected wounds are packed with an antibiotic dressing such as nitrofurazone ointment for 24 to 48 hours before attempting closure.

Surgery may be performed with the horse under general anesthesia or with sedation and nerve blocks, depending on the extent of the injury. Surgical preparation is performed with diluted povidone-iodine solution (see Chapter 55). Necrotic tissue should be excised, but debridement should not be excessive. In particular, an attempt should be made to preserve as much of the eyelid margin as possible. Defects involving up to one third of the eyelid margin may be closed by direct suturing without creating excessive tension. Larger defects require other blepharoplastic techniques. Closure is performed in two layers. The palpebral conjunctiva is closed using 4-0 to 6-0 absorbable suture material such as polyglactin 910 (Vicryl, Ethicon, Somerville, NJ) in a simple-interrupted or continuous pattern, starting near the eyelid margin. Knots should be buried to avoid corneal irritation (Fig. 56-7).

Closure of the skin should always start at the eyelid margin to ensure optimal apposition and proper eyelid function. A simple-interrupted suture pattern using 4-0 or 5-0 nonabsorbable material provides maximal apposition of the wound edges. A figure-eight suture placed at the eyelid margin (see Fig. 56-7) allows the placement of the suture directly at the eyelid margin but avoids a knot being placed at the margin, which could cause corneal irritation. Alternatively, a simple-interrupted suture can be placed at the margin, with long suture ends left on the knot. These ends can be incorporated into the knot of the second suture to direct the first knot away from the cornea.

Habronema
Adult Habronema—before the introduction of ivermectin, a frequent problem in horses—live in the equine stomach, where they are generally asymptomatic. Larvae are passed in the feces, where they are ingested by house fly or stable fly larvae, which act as intermediate hosts. The Habronema larvae develop to an infective third-stage larva (L3) in the pupating fly. As the adult fly feeds on the horse, L3 may be deposited in wounds or periocular structures, which may lead to clinical habronemiasis (summer sores).

Adnexal habronemiasis may be unilateral or bilateral and is most common during the summer months. Clinical signs include nodular or ulcerative blepharitis and conjunctivitis. The presence of multiple yellow “sulfur granules” within the conjunctiva is considered pathognomonic.21-23 The medial canthal area is frequently involved, and nasolacrimal duct involvement caused by migration of larvae may result in a circular lesion 1 to 5 cm below the canthus. Corneal ulceration caused by abrasion of conjunctival masses is common.
Although the granulomatous nature of these lesions is frequently characteristic, histopathology or fine-needle aspiration is recommended to distinguish these lesions from squamous cell carcinoma, sarcoids, or other palpebral neoplasias. Mast cells and eosinophils are frequently present in high numbers.

Medical management is directed toward removing the aberrant larvae and controlling secondary infection and inflammation. Topical ophthalmic antibiotics and corticosteroids (in the absence of corneal ulcers) are often helpful. Ivermectin (Eqvylan, MSD-AGVET, Rahway, NJ) at 0.02 mg/kg IM, has a larvicidal effect. Oral diethylcarbamazine at 6 mg/kg daily for 21 days may also be effective and may be used prophylactically during fly season.

Probably the most practical medical therapy is the systemic use of ivermectin as a larvicide, with an antibiotic plus corticosteroid preparation applied topically. The use of ointments provides longer contact time than ophthalmic solutions. Systemic or intralesional corticosteroids may be indicated to help control the hypersensitivity reaction to the larvae. Fly control to prevent reinfection is recommended.

Recovery may be hastened by surgical intervention. Removal of granulomatous lesions from conjunctival surfaces may prevent the development of secondary corneal ulcers. Debridement of palpebral lesions removes necrotic debris as well as Habronema larvae, which act as an antigenic source, and speeds their resolution.

Recovery may be hastened by surgical intervention. Removal of granulomatous lesions from conjunctival surfaces may prevent the development of secondary corneal ulcers. Debridement of palpebral lesions removes necrotic debris as well as Habronema larvae, which act as an antigenic source, and speeds their resolution.

Eyelid Neoplasia

A number of eyelid tumors have been reported in the horse, including squamous cell carcinomas, equine sarcoids, fibromas, schwannomas, melanomas, basal cell carcinomas, papillomas, hemangiosarcomas, lymphosarcomas, mastocytomas, and adenocarcinomas. Of these, squamous cell carcinoma is by far the most common tumor in the horse associated with the eye, followed by sarcoids. All other tumor types are rare. Histopathology or fine-needle aspiration for cytology is recommended to differentiate tumor types and to distinguish them from inflammatory lesions. Papilloma, the third most common eyelid tumor, is usually seen in young horses. It is usually self-limiting and does not require treatment.

Squamous Cell Carcinoma

Squamous cell carcinoma may involve the eyelid, the third eyelid, and the globe. Lesions are not uncommonly bilateral but are not necessarily symmetric. Draft breeds may be predisposed to this tumor. Horses with nonpigmented eyelids may possibly be at increased risk as well. The average age of affected horses is 8 to 11 years.

The clinical appearance of squamous cell carcinoma is variable. Early tumors resemble a mild inflammatory reaction. As the tumor progresses, it may appear proliferative or ulcerative. Tumors are locally invasive with a high rate of recurrence and a significant rate of systemic metastasis (6% to 15%).

Modes of therapy include excision, alone or in combination with other procedures; hyperthermia; cryotherapy; radiation therapy; immunotherapy; chemotheraphy; and laser therapy. Excision of masses involving removal of up to one third of the eyelid margin may be repaired by simple closure. More extensive excisions require reconstructive efforts (see "Blepharoplasty," p. 709). All surgical margins should be examined histopathologically.

Hypothermia

Hyperthermia is easily performed and well tolerated by ocular tissue. Large tumors should be debulked prior to hyperthermia. Surface probes should be pressed against the tumor to ensure contact adequate to provide uniform
heating (RF-22 Thermoprobe, Hach Chemical Company, Loveland, Colo). Treatment is maintained for 30 seconds after 50°C (122°F) is reached. Many units have an audible signal when the therapeutic temperature is reached, which may startle the horse during standing procedures. Deep palpebral lesions require the use of piercing probes, which should be applied at 2- to 3-mm intervals. Most eyelid tumors slough within 7 to 10 days, leaving a granulating wound. Cosmetic results are usually good, although depigmentation may occur. A high rate of regression has been reported. The usefulness of this procedure is limited by tumor size.

CRYOTHERAPY
Cryotherapy has the advantages of sparing normal tissues and of possibly stimulating the immune system against the neoplastic cells. Liquid nitrogen is the preferred cryogen because of its ability to produce a fast, deep freeze (see Chapter 15). The use of nitrous oxide is limited to smaller, more superficial masses (See “Sarcoids,” later). Success rates are approximately 80% with a single treatment.

RADIATION THERAPY
Radiation therapy may be divided into teletherapy, interstitial therapy, and β-radiation. Teletherapy is capable of delivering high doses of radiation but has the disadvantage of requiring fractionation of the dose, necessitating repeated weekly general anesthesia. Strontium-90 may be applied topically as a source of β-radiation. Although β-radiation is useful for tumors involving the globe, it may be limited in palpebral tumors because of its poor penetration. For this reason, tumors should be debulked to a thickness of less than 2 mm. Recurrence rates may be as low as 11%. Although β-radiation is well tolerated, chronic keratopathy has been reported.

Interstitial therapy, which has been reported with iridium-192, gold-198, and cobalt-60, has the advantage of direct placement of the radiation source into the tumor, providing a high radiation dose to the mass. The continuous irradiation may increase the efficacy of radiation therapy. The use of interstitial implantation is restricted to licensed facilities and operators. The horse must be considered a radiation hazard during the period of implantation, which is usually 7 to 10 days, necessitating quarantine. Success rates of 73% to 90% have been reported. Cosmetic results are generally good, with alopecia and depigmentation representing common side effects. Eyelid fibrosis, cataract, and keratitis with corneal ulcers are also possible complications, the incidence of which is radiation dose dependent.

IMMUNOTHERAPY
Immunotherapy of equine squamous cell carcinoma using local infiltration of bacille Calmette-Guérin (BCG) cell wall emulsion has been described. In a single case report, there was regression of both the primary periorcular tumor and an untreated metastatic lymph node lesion.

CHEMOTHERAPY
Cisplatin has been used to treat squamous cell carcinoma and equine sarcoid by intratumoral injection. Emulsions in sesame oil, containing 3.3 mg of cisplatin per milliliter of emulsion, were injected into the tumor at a dosage of 1 mg cisplatin per cubic centimeter of tumor mass. Injections were repeated four times at 2-week intervals, perfusing a treatment field that encompassed a 1-cm margin around the gross lesion. Tumor regression was seen in all cases, and complete regression was seen in 5 of 7 squamous cell carcinomas and in 4 of 4 squamous cell papillomas, with a mean relapse-free interval of 14 months (see Chapter 29).

LASER EXCISION
Ablation by a carbon dioxide laser has been reported for the treatment of limbal squamous cell carcinoma. General anesthesia is preferred to local anesthesia because inadvertent tissue burns associated with patient movement may be avoided. A defocused laser beam is applied to provide ablation rather than cutting. Laser ablation may provide advantages of improved control of hemorrhage and decreased discomfort postoperatively, and it may serve to enhance the antitumor immune response. Disadvantages include prolonged wound healing time and high cost of equipment.

Sarcoids
Sarcoids are locally invasive fibroblastic tumors with a variable epithelial component. The sarcoid is the most common skin tumor in the horse, second only to squamous cell carcinoma in frequency of eyelid involvement. The histopathologic classification of sarcoids is controversial. Some authors consider a sarcoid to represent a distinct pathologic entity, and others make no distinction between sarcoids and other fibrous tumors. Biopsy is recommended for diagnosis. Clinically, the sarcoid may be classified as verrucous, fibroblastic, or mixed types, occurring in two growth patterns—sessile or pedunculated (see Chapter 29). Electron microscopic studies and viral cultures support a viral cause for the tumor. The retrovirus suggested by initial studies was later characterized as an endogenous virus. More recent studies suggest a bovine papilloma virus as a causative agent. Sarcoïds may be transferred experimentally. Younger horses are more commonly affected, with a mean age of 3 to 5 years. There may also be an association between increased incidence and recurrence rates and equine leucocyte antigens.

Sarcoids may be treated by a variety of methods, including surgical excision, hyperthermia, cryotherapy, irradiation, immunotherapy, and chemotherapy.

SURGICAL EXCISION
Surgical excision by itself has a high recurrence rate (up to 50%). However, surgical debulking is frequently performed when using other treatment modalities. Combination therapy may be particularly helpful when the involvement of the eyelid precludes total excision.

Laser ablation or excision can also be performed. Tissue handling can be reduced, and cosmetic results are usually good. However, wound healing may be prolonged. The recurrence rate has been reported to be comparable to that of conventional excision when used as the sole modality of treatment, but other reviews suggest there may be a definite advantage to using laser.
HYPERDERMIC INJECTIONS

Hyperdermic injections are usually performed under local anesthesia and are well tolerated by horses. Common sites include the dorsal roof of the mouth, the neck, and the ventral abdomen. The needle is inserted subcutaneously, and the medication is administered at a dose of 1 to 2 mg/kg intramuscularly or subcutaneously. The needle is removed, and pressure is applied to the site to prevent bleeding. The site of injection may be dressed with a sterile bandage. In horses with multiple sarcoids, treatment of each lesion may be required.

OTHER METHODS

Other methods of removing sarcoids have appeared in the literature, such as topical 5-fluorouracil, topical idoxuridine, and topical podophyllum application. These therapies have not gained general acceptance.

Special Surgical Techniques

Blepharoplasty

Reconstructive blepharoplasty is indicated in any horse in which trauma or surgical excision has removed more than one third of the eyelid margin. This type of surgery is best performed under general anesthesia. It should be remembered that although the eyelid skin is pliable, the surrounding facial skin is relatively inelastic and may not stretch readily to provide donor skin.

SLIDING SKIN FLAP

The simplest form of blepharoplasty is the sliding skin flap (Fig. 56-8). After excision of affected tissue, the incisions are extended vertically for twice the height of the excised portion. Slightly diverging incisions allow for wound contraction. Triangular pieces of skin should be excised at the end of each incision. These triangles facilitate closure without skin folds (dog-ears) and help to distribute tension. The sides of the triangle should approximate the height of the excised portion. Surrounding skin should be
undermined with scissors to provide skin mobility. Adjacent conjunctiva should also be mobilized to cover the defect, if possible. Skin closure should begin at the eyelid margin using a 4-0 nonabsorbable suture material. A slight over-correction—that is, bringing the flap slightly beyond the desired level of the eyelid margin—may result in a better cosmetic result after wound contracture occurs. The flap should be sutured to the underlying conjunctiva along the eyelid margin with 6-0 absorbable suture (e.g., polyglactin 910) in a simple continuous pattern. If tension exists on the skin flap, additional support may be provided by performing a temporary tarsorrhaphy.

CONJUNCTIVAL ADVANCEMENT FLAP

In cases with extensive conjunctival involvement, a conjunctival advancement flap from the opposing eyelid may be required (Fig. 56-9). The conjunctiva should be incised 3 to 4 mm from the eyelid margin, and it is undermined to create a flap, which is sutured to the opposing conjunctiva. The skin flap is performed as already described. A temporary tarsorrhaphy is required to relieve tension on the conjunctival flap. A second surgical procedure is required to cut the conjunctival flap to restore the eyelid margin. This procedure should not be performed for at least 1 month after the primary surgery.
FULL-THICKNESS EYELID GRAFT
A full-thickness eyelid graft may be required because of the poor mobility of facial skin (Fig. 56-10). This technique is best suited for a graft for a lower eyelid defect, because the upper eyelid is larger and more mobile, providing a better donor flap. The width of the graft should approximate the width of the defect. In extensive defects, a lateral canthotomy to release tension may be helpful. The opposing eyelid is incised approximately 5 mm above the eyelid margin to avoid the tarsal glands. Splitting the graft into skin-muscle and tarsocconjunctival layers improves mobility, reducing the size of the graft required. A sliding skin flap is prepared on the lower eyelid. The tarsocconjunctival layers are closed with 6-0 absorbable sutures, with knots buried to prevent corneal contact. The skin is closed with 4-0 nonabsorbable sutures, such as silk or nylon. The bridge is sutured to the graft to prevent retraction. The flap is left in place until tension has dissipated, which may take several weeks. In a second procedure, the flap is transected along the new eyelid margin and sutured to the bridge. The new eyelid margin is sutured with 6-0 absorbable sutures to appose conjunctiva and skin.

RHOMBOID GRAFT FLAP
A rhomboid graft flap for repairing defects involving more than 50% of the eyelid has been described (Fig. 56-11). The rhomboid is an equal-sided parallelogram and can be constructed with sides at 90 degrees (square) or at 60 and 120 degrees. One side of the rhomboid assumes the position of the eyelid margin. The replacement flap is constructed by two incisions, the first being an extension of the diagonal of the rhomboid and equal in length to the sides of the rhombus. The second incision is made parallel to the rhombus for an equal distance. Conjunctiva from the eyelid or globe should be identified for use in closure. The skin is undermined and rotated to fill the defect. The skin is closed with simple-interrupted 4-0 nonabsorbable sutures. The conjunctiva is sutured to the skin flap to form an eyelid.

Figure 56-10. Full-thickness eyelid graft. A, The area of affected lower eyelid is excised. B, The upper eyelid is excised 5 mm above the eyelid margin opposite the defect. C, The graft is split into skin and tarsocconjunctival layers. The graft is advanced under the eyelid margin and sutured in place. D, The bridging eyelid margin is sutured to the graft. A temporary tarsorrhaphy alleviates tension on the graft. E, After adequate healing has occurred, the graft is severed along the intended eyelid margin. F, The conjunctiva and skin are apposed along the eyelid margin with a continuous suture pattern. The skin flap is sutured to the bridge to complete the closure.
margin using 6-0 absorbable suture material in a simple-continuous pattern. It is advisable to draw the proposed incisions on the skin with a surgical marker prior to surgery for optimal results.

SLIDING Z FLAP
Defects in the lateral upper eyelid can be closed with a sliding Z flap (Fig. 56-12). After excision of the lesion, adjacent conjunctiva is undermined and apposed with 6-0 absorbable sutures. The surrounding skin is undermined. Triangles of skin are excised above and below the defect. The bases of these triangles are aligned on the diagonal of the defect, and the sides are equal to the width of the defect. Again, it may be helpful to draw the proposed incision lines on the skin with a surgical marker prior to beginning surgery to ensure proper orientation of incisions.

Other types of skin flaps and reconstructive techniques applicable to the horse may be found in human and small animal ophthalmology texts, or in equine surgical case reports.

PARTIAL ORBITAL RIM RESECTION
In cases requiring radical resection of the periocular tissue combined with enucleation or exenteration, there may be inadequate tissue to close the skin using conventional reconstructive techniques. In this technique, the caudal portion of the dorsal orbital rim is resected after enucleation to reduce the wound size and reduce tension on the closure. Extensive

Figure 56-11. Rhomboid graft flap. A, The rhomboid is aligned with one side along the position of the eyelid margin. Sides of the rhomboid are equal. The replacement flap is incised on a line (A1) continuous with the diagonal of the rhomboid, for a distance equal to the sides of the rhomboid. The second incision (A2) is also equal in length, and is placed parallel to the side of the rhomboid. B, The lesion is excised and conjunctiva is mobilized to cover the replacement flap. C, The flap is dissected free from underlying tissue and rotated into position. D, The flap is sutured in position with the leading edge forming the new eyelid margin. (Angles 1 and 2 are indicated on B and D to aid in orientation.)

Figure 56-12. Sliding Z flap. A, Growths of the lateral eyelid can be removed en bloc. The triangular areas of skin to be removed adjacent to the defect are marked. Excision of these flaps facilitates skin mobilization. (The bases of the triangles align with the diagonal of the defect.) B, Adjacent skin is undermined. C, Equivalent triangles of skin are excised. (Cut edges A, A’, B, and B’ are shown to aid in orientation for advancement of the flap.) D, The flap is advanced and sutured in place.
undermining of adjacent skin and mesh skin expansion are required to permit advancement and closure of the wound.33

**Tarsorrhaphy**

Tarsorrhaphies may be temporary or permanent, depending on whether the eyelid margins are excised prior to suturing. A tarsorrhaphy is indicated for protection of the cornea in cases of facial paralysis or when eyelid swelling causes the loss of the ability to close the eye; after corneal surgery, to provide additional support to the globe; and after eyelid surgery, to allow the normal eyelid to “splint” the affected eyelid to reduce the risk of wound dehiscence or eyelid distortion.

**TEMPORARY TARSORRHAPHY**

A temporary tarsorrhaphy is adequate for most cases and can be performed in the standing animal with the use of sedation, regional nerve blocks, and topical anesthesia. Preparation of the eye region for aseptic surgery should be performed. Three or four horizontal mattress sutures are spaced along the palpebral fissure to distribute the tension. It is usually helpful to leave the medial canthus slightly open to facilitate drainage. A relatively heavy nonabsorbable suture material (e.g., 2-0 or 3-0 monofilament nylon or silk) should be placed in partial thickness to avoid contact with the cornea (Fig. 56-13). The use of rubber tubing or button stents helps to prevent sutures cutting into the eyelid.

**PERMANENT TARSORRHAPHY**

If extended closure is anticipated, such as in facial paralysis, a permanent tarsorrhaphy is recommended (Fig. 56-14). This is similar to the temporary tarsorrhaphy, except that the eyelid margin is excised at the site of each suture placement. This method facilitates eyelid adhesion along these sites after the sutures are removed. It can be left for prolonged periods while waiting for neurologic improvement. When the tarsorrhaphy is no longer required, the adhered regions of eyelid margin can be incised with scissors to restore the palpebral fissure.

**AFTERCARE**

The principles of aftercare for eyelid surgery are the same as for surgical procedures elsewhere on the skin. Perioperative topical and systemic broad-spectrum antibiotics are frequently indicated. The placement of a subpalpebral lavage system or a nasolacrimal medication catheter may greatly facilitate topical therapy.

Postoperative swelling may be minimized by the use of ice packs in the immediate postoperative period. If swelling is present for more than 24 to 48 hours after surgery, warm compresses may reduce swelling and discomfort. The use of flunixin meglumine at 1 mg/kg IV immediately prior to surgery greatly reduces postoperative swelling. Dimethyl sulfoxide applied to the periorbital skin also reduces post-

---

**Figure 56-13.** Temporary tarsorrhaphy. **A,** Sutures should be preplaced to distribute tension. **B,** Sutures should be placed at partial thickness, crossing the eyelid margin at the level of the meibomian gland openings. **C,** Sutures are tied. The use of stents reduces the risk of sutures cutting into the eyelids.

**Figure 56-14.** Permanent tarsorrhaphy. **A,** Opposing areas of eyelid margin (approximately 3 mm long) are excised with a #11 Bard-Parker scalpel blade. **B,** Sutures are placed in the areas of excised margin. Sutures should be left in place for 3 weeks to allow eyelid adhesion.
operative inflammation. Care should be taken to avoid inadvertent application to the eye.

In procedures such as cryotherapy and immunotherapy, which create granulating wounds, removal of exudate by frequent cleaning and fly control are important for patient comfort. Fly control may be achieved by wiping fly repellant around the surgical site, by allowing the horse to wear a fly screen face cover, or by using fly-repellent halter strips.

If discomfort occurs, the surgical site must be protected against rubbing and self-mutilation. Neck cradles or cross-tying may restrict activity adequately. A hood with an eyecup is also helpful (Eyesaver, Pasadena, Calif.).

In many cases, skin sutures may be removed as early as 7 to 10 days postoperatively. Sutures in horses with tension on skin flaps, for example, must remain longer.

REFERENCES

ANATOMY

The conjunctiva is a thin mucous membrane that extends from the limbus of the eye to the margin of the eyelids. The part of the conjunctiva covering the anterior portion of the sclera is the bulbar conjunctiva. It is reflected at the conjunctival fornix to line the inner surface of the eyelids as the palpebral conjunctiva and to cover the third eyelid. The space bordered by the conjunctival and corneal surfaces is the conjunctival sac (Fig. 57-1).

The palpebral conjunctiva is firmly attached to the underlying tarsal collagenous connective tissue. At the medial canthus, horses, unlike small animals, have a small fleshy protrusion, the lacrimal caruncle, which consists of modified skin surrounded by palpebral conjunctiva. The bulbar conjunctiva is loosely attached to the globe except near the limbus, where its deeper layer blends with the attachments of the underlying Tenon’s capsule (a thin fascial coat that envelops the globe). Dissection of the conjunctiva from the globe is therefore more difficult immediately behind the limbus. The conjunctiva of the upper lid near the fornix is penetrated by 12 to 16 ducts of the lacrimal gland.

The conjunctiva is divided histologically into two layers: a superficial layer of stratified columnar epithelium, which is continuous with the stratified squamous epithelium of the cornea, and a deeper substantia propria. The substantia propria at the fornices is complemented by fascial attachments of the eyelid and extraocular muscles that hold the fornices in place. The palpebral conjunctival epithelium contains goblet cells that are particularly numerous at the fornices and over the base of the anterior surface of the third eyelid. The conjunctival epithelium may be variably pigmented and is particularly so in the horse near the limbus and at the margin of the third eyelid.

The substantia propria has a superficial glandular layer and a deeper layer of loose fibrous tissue. Two layers of lymphatics are present, one at the depth of the superficial blood vessels and the other in the deep fibrous layer. Lymph follicles are especially numerous in the bulbar conjunctiva of the third eyelid and fornices.

Surgically, the conjunctiva can be divided into the superficial epithelial layer and the subepithelial fibrous layer, to which the epithelial layer is anchored by subepithelial fibers. A potential space, the episcleral space, lies between the fibrous layer and the globe, ending a few millimeters behind the limbus where the conjunctiva and Tenon’s capsule fuse.

The blood supply to the conjunctiva is derived from the anterior ciliary arteries and the vascular arcades of the eyelids. The deep anterior ciliary vessels, which are straight and deep red, can be seen beneath the bulbar conjunctiva near the limbus, where they communicate with the finer, pinker, and more tortuous superficial conjunctival blood vessels. These conjunctival vessels radiate from the limbus toward the fornix.

The conjunctiva receives sensory innervation from the trigeminal nerve.

PATHOPHYSIOLOGY

The conjunctiva responds to injury with vascular dilatation and edema. Lacerations heal quickly. The edges of the defect adhere to the underlying palpebral tarsus or episclera and Tenon’s capsule. Epithelial cells slide into the area of the defect, and the conjunctival surface is subsequently reformed by mitosis of adjacent basal cells.

The dense vascular arcades and lymphatics in the conjunctiva predispose it to become inflamed in response to many irritants and infectious organisms. In acute conjunctivitis, the conjunctiva is injected or hyperemic and edematous, and inflammatory cell infiltration may be seen histologically. In chronic conjunctivitis, the conjunctiva becomes hypertrophic and lymphoid follicles become enlarged and prominent. Pseudodiphtheritic and diphtheritic membranes may develop. Hyperemia of deep ciliary vessels can be differentiated from superficial vessels in the bulbar conjunctiva by their deeper red color, straight course, and immobility when the bulbar conjunctiva is moved. Application of topical 2.5% phenylephrine (Mydfrin, Alcon Laboratories, Inc, Fort Worth, Tex) frequently blanches superficial but not deeper blood vessels. Conjunctival swelling
may be caused by edema (chemosis) and inflammatory or neoplastic cell infiltrates.

**DIAGNOSTIC PROCEDURES**

The conjunctiva should be examined with a good light source for color change, irregularities of the surface, and swellings. The conjunctiva is best examined after performing an auriculopalpebral nerve block (see Chapter 55). The lids should be retracted from the globe to allow examination of the conjunctival fornices for foreign bodies and irregularities. After applying topical proparacaine hydrochloride, the conjunctival surface can be palpated gently with the index finger. This is especially important when assessing the extent of spread of conjunctival neoplasms, which may be better felt than seen.

Conjunctival cytology and subconjunctival aspiration can be valuable in cases where conjunctivitis or conjunctival masses are present. After applying topical anesthetic, the conjunctival surfaces are scraped using either a platinum Kimura spatula, the hub end of a scalpel blade, or a cotton-tipped applicator. Smears are made and stained using the Giemsa and Gram technique.

Conjunctival biopsies are essential in making a diagnosis in cases of potential neoplasia and may be of value diagnostically in some cases of conjunctivitis (for instance, habronemiasis). After applying topical proparacaine, a small area of a lesion can be excised with tenotomy scissors.

**CONJUNCTIVAL SURGERY**

The layers of conjunctiva sectioned during surgery depend on the procedure being performed. In preparing a conjunctival flap, the dissection should involve only the epithelial layer, with as little subepithelial fibrous tissue as possible. The epithelial layer has an extensive surface area and considerable elasticity. Incorporation of the underlying fibrous layer reduces the elasticity and consequently promotes tearing of the flap after surgery. The epithelial layer, however, is thin and can easily be torn or perforated during dissection by rough tissue handling. For removal of conjunctival neoplasms, resection of the conjunctiva to the episcleral space is recommended.

**Dissection**

Dissection of the conjunctiva requires fine-toothed forceps (Colibri forceps) and semiblunt-tipped scissors (Stevens tenotomy scissors). Incisions into the conjunctiva can be made either with short strokes of a rounded blade or with the scissors. Incisions with scissors should, whenever possible, be carried out with the scissors tip to avoid pulling excess tissue into the scissor blades as they are closed because of the elastic nature of the epithelial layer. At sites where the conjunctiva is anchored, and particularly adjacent to the limbus, there is a greater tendency to perforate the tissue during dissection. Small instrument excursions when cutting the subepithelial fibers reduce the risk of perforations. Additionally, elevation of the conjunctiva tenses the subepithelial fibers and increases the ease with which fibers are cut, reducing the risk of drawing the epithelial layer into the path of the scissor blade.

**Suturing**

Suturing the conjunctiva requires fine-tipped forceps and absorbable 6-0 to 7-0 suture material (polyglycolic acid or polyglactin 910). Nonabsorbable sutures are rarely used in the horse for conjunctival suturing because of the inconvenience of later removal. Swaged-on taper-point or spatula needles are used.

**Conjunctival Flaps**

To prepare a conjunctival flap, a portion of the conjunctiva is incised from the limbus or fornix, dissected from underlying tissues, and advanced over the corneal surface. When covering a corneal defect, a conjunctival flap provides blood supply and nutrition and potentiates the immune response against infectious agents attacking the cornea. Rarely is a conjunctival flap thick enough to provide any significant physical support for a thinned cornea. General anesthesia is essential to place a conjunctival flap.

Conjunctival flaps are indicated for ulcerative keratitis when the corneal ulcer extends into the corneal stroma. Although conjunctival flaps can be used for superficial corneal ulcers that are refractory to medical therapy, this is usually not necessary. The value of conjunctival flaps for deep corneal ulcers is debatable, particularly if the ulcer extends to Descemet’s membrane (descemetoecele). Because conjunctival flaps provide little support for the cornea, techniques that move corneal tissue to provide support are more appropriate for descemetoeceles of more than a few millimeters in diameter. If the descemetoecele is less than 5 mm in diameter, a conjunctival flap is often sufficient if surgical rather than medical therapy is elected. When a deep corneal ulcer cannot be intensively medicated (frequently around the clock), surgical therapy should be considered. The decision to proceed with surgical therapy has to be weighed against the risk of corneal perforation that might occur during anesthetic induction or recovery. Corneal ulcers that undergo rapid stromal enzymatic breakdown (melting ulcers) would benefit from a conjunctival flap, but rarely do they have healthy-enough corneal tissue to hold sutures of a pedicle or 180-degree conjunctival flap. A 360-degree flap that does not involve suture placement in the cornea is more appropriate in this situation.

Various types of conjunctival flaps can be used in horses, including pedicle flaps (dissected from either bulbar or tarsal conjunctiva), bridge flaps of bulbar conjunctiva, and 180-degree hood flaps. Complete (360-degree) flaps of bulbar conjunctiva can be used, although because of the friable nature of the equine conjunctiva, they are more difficult to dissect than in small animals and are more prone to retract soon after surgery.

**Pedicle Flap**

A pedicle flap of bulbar conjunctiva is indicated for a corneal ulcer involving the peripheral cornea in any quadrant. The bulbar conjunctiva is grasped 1 to 2 mm behind
the limbus with Colibri corneal fixation forceps and is slightly elevated, and a small conjunctival incision is made with tenotomy scissors. The tips of the scissors are used to open the incision and bluntly dissect the conjunctival epithelium from the underlying fascia. The incision is continued parallel to the limbus for about one third of the corneal circumference, centered adjacent to the corneal ulcer (Fig. 57-2). The bulbar conjunctiva is subsequently dissected bluntly with tenotomy scissors from the underlying fascia back toward the fornix. At one end of the limbal incision, the conjunctiva is incised in a radial direction at 90 degrees to the limbus for a distance equal to the width of the flap required.

Dissection of the flap is completed by continuing the incision parallel to the initial limbal incision to create a pedicle of conjunctiva with a wide base. The width of the pedicle is largely determined by the width of the corneal ulcer and should be large enough to cover the defect and a few millimeters of healthy cornea on either side, without undue stretching of the tissues involved. The extra width allows for contraction after surgery without applying excessive tension on the sutures. The incision farthest from the limbus should be shorter than the first incision to ensure that the base of the flap has an adequate blood supply from radially oriented conjunctival vessels. If dissected well, the conjunctival flap will be a thin, semitransparent layer that will cover the ulcer when reflected onto the cornea without stretching or retraction. The area of corneal epithelium 1 to 2 mm around the corneal ulcer is débrided with a Beaver blade to expose stroma to which the conjunctival flap can adhere. The flap is sutured to the cornea using absorbable sutures, 6-0 or 7-0 polyglycolic acid or polyglactin 910, with a swaged-on micropoint spatula needle penetrating from half to two thirds of the corneal depth. The needle should pass through the conjunctiva, enter the edge of the ulcer, and emerge from the cornea 2 to 3 mm from the ulcer edge. Usually, four to eight sutures are adequate. The exposed area of bulbar conjunctiva from where the flap was dissected can be closed with the same suture material in a simple-continuous pattern. Small defects in the bulbar conjunctiva can be left to heal by second intention.

Tarsoconjunctival pedicle grafts can also be used to provide blood supply and support to a deeply ulcerated or perforated cornea. A pedicle of tarsoconjunctiva is excised from the middle third of the inside of the upper eyelid, leaving an attachment at the eyelid margin. The flap is rotated so that the deep tarsoconjunctival tissue faces the cornea, and the graft is sutured over the area of the corneal lesion with absorbable sutures. After 2 to 3 weeks, the flap is transected from the upper eyelid, and loose excess tissue is excised from the corneal attachments.

Bridge Flap

A bridge flap is indicated for central corneal ulcers. Ideally, the flap is dissected from the lateral bulbar conjunctiva so that it is oriented vertically across the corneal surface. This way, tension on the flap and sutures is reduced during movement of the eyelids over the flap surface. The conjunctiva is dissected free from the limbus from 160 to 180 degrees and bluntly dissected back toward the fornix with tenotomy scissors. Care must be taken to keep the dissection of the conjunctiva as superficial as possible. A second incision is made with tenotomy scissors, parallel to the first one and abaxially, except at the ends, where it diverges away from the first incision toward the fornix (Fig. 57-3). The distance between the two parallel incisions (i.e., the width of the flap) is determined by the width of the corneal lesion to be covered. As with a pedicle flap, the second incision should be no longer than the perilimbal incision to allow blood vessels to enter the flap. The flap, attached at two

Figure 57-2. Pedicle conjunctival flap. A, The pedicle is bluntly dissected from underlying fibrous tissue. B, The pedicle should lie over the corneal defect without undue tension. C, The pedicle is sutured around the edge of the corneal lesion.

Figure 57-3. Bridge conjunctival flap. A, A strip of conjunctiva is incised and bluntly dissected from the bulbar conjunctiva. B, The bridge of conjunctiva is sutured to the cornea around the edge of the corneal ulcer.
ends, is subsequently transferred to the cornea and sutured around the edges of the corneal ulcer with simple-interrupted sutures of 6-0 or 7-0 polyglycolic acid or polyglactin 910. Additional sutures are placed in the episclera adjacent to the limbus at either end of the flap. The exposed area of sclera behind the limbus from which the flap was dissected is covered with bulbar conjunctiva pulled from the fornix and sutured to the perilimbal episclera with the same suture material in a simple-continuous pattern. Bridge and pedicle flaps can be dissected medially to cover medial corneal lesions if necessary, although the manner in which the bulbar conjunctiva is reflected onto the inner surface of the third eyelid may hinder dissection.

Both pedicle and bridge flaps are left in place for 14 to 21 days, or longer, until the area of the corneal ulcer is vascularized and granulation tissue can be seen around the edge of the flap. The flap often adheres to the edges of the ulcer. Some flaps may retract from the cornea on their own, and others may become cornea-like in appearance. Conjunctival flaps, however, can easily be removed from the cornea once their presence is no longer needed. Using sedation, an auriculopalpebral nerve block, and topical proparacaine anesthesia of the cornea and conjunctiva, the flap is trimmed away around the area of the ulcer and redundant conjunctival tissue excised.

The 180-Degree Flap
The 180-degree conjunctival flap is indicated for the treatment of a large area of corneal ulceration involving the peripheral cornea. A 180-degree incision is made into the conjunctiva 1 to 2 mm behind the limbus. Using tenotomy scissors, the conjunctiva is gently undermined toward the fornix (Fig. 57-4). It is especially important to keep the flap as thin as possible and not to incorporate subepithelial fascia when dissecting a 180-degree flap. If the flap is dissected satisfactorily, it can be advanced onto the cornea. Minimal flap retraction will occur. If the flap is too thick and has subepithelial fascia incorporated, undue tension will be needed to move the flap over the corneal surface, resulting in retraction of the flap within a few days of surgery. A flap containing too much subepithelial fibrous tissue should have the fibrous tissue gently dissected from the epithelial layer before attempting to suture it to the cornea. The flap is sutured to the episclera at the ends of the incision and to the cornea with several sutures of 6-0 or 7-0 polyglycolic acid or polyglactin 910 using a swaged-on micropoint spatula needle penetrating one half to two thirds of the corneal depth. The flap will retract as the sutures are absorbed, or it can be released after 14 to 21 days by removing the sutures.

The 360-Degree Flap
Conjunctival flaps of 360 degrees are dissected in the same way as 180-degree flaps, but the incision is extended around the entire limbus (Fig. 57-5). The conjunctival flaps from the superior and inferior hemispheres are advanced onto the cornea and sutured together using interrupted horizontal mattress sutures of 6-0 silk. Using a 360-degree flap avoids the need to place sutures into the cornea itself. The silk sutures are removed after 10 to 14 days and the conjunctiva is allowed to retract.

Limbal-Based Flap
Limbal-based flaps involve making incisions into the conjunctiva at some distance between the limbus and the fornix and inverting the conjunctiva (hinged at the limbus) over the cornea so that its exterior surface contacts the corneal surface. These flaps are used less in veterinary than
in human ophthalmology, although there is no reason why they cannot be applied in horses.

**SURGICAL DISORDERS**

**Dermoids**

Dermoids are occasionally seen in horses (Fig. 57-6). Although these need not cause significant impairment of vision, some involving the conjunctiva may encroach onto the cornea and pigment it, causing some visual handicap. Dermoids are excised from the cornea with a superficial keratectomy, and areas of involved conjunctiva are excised using tenotomy scissors. The exposed episclera can be repaired by apposing the edges of bulbar conjunctiva with absorbable suture (polyglactin 910 or polyglycolic acid) in a simple-continuous suture pattern.

**Lacerations**

Small lacerations of the conjunctiva require no surgical treatment and heal rapidly by second intention. Large defects can be repaired by suturing the cut edges with absorbable suture. Lacerations involving the palpebral (tarsal) conjunctiva should be sutured using a simple-continuous pattern with buried knots to avoid having the suture material abrade the cornea. Local invasion of ocular and periocular tissues occurs and may involve the globe and adnexa, the bony orbit, paranasal sinuses, and brain. It is often impossible from the clinical appearance to determine whether the tumor has started to invade adjacent structures. Digital palpation of the conjunctival sac after auriculopalpebral and topical anesthesia is a useful means of determining the extent of the conjunctival involvement. Skull radiography or computed tomography (where available) aids in determining whether the tumor has invaded adjacent orbital bone. Metastasis occurs to regional lymph nodes, parotid salivary glands, and lymph nodes of the cervical chain and mediastinum in up to 15% of cases. The primary differential diagnoses for conjunctival squamous cell carcinoma are habronemiasis, conjunctivitis, and other neoplasms.

All lesions suspected as being squamous cell carcinomas should undergo biopsy for histopathology. The tumor is often quite friable, and impression smears may be used for an early diagnosis. The clinical appearance of squamous cell carcinoma is not diagnostic per se, and confirmation must rely on histopathologic examination.

**TREATMENT**

Treatment of conjunctival squamous cell carcinoma depends on the size of the tumor and involvement of other ocular structures. It includes surgical excision, radiation therapy, orbital exenteration, cryotherapy, and hyperthermia.

**Surgical excision**

Small areas of conjunctival tumor can be removed by excision. Care should be taken to excise as wide a margin as possible (at least 3 mm). The margins of the conjunctiva can be sutured prior to irradiation to reduce the conjunctival reaction.

**Radiation therapy**

Radiation therapy is a valuable additional means of treating conjunctival squamous cell carcinoma. For debulked conjunctival squamous cell tumors, $\gamma$-irradiation with a strontium-90 probe is suitable when the tumor bed is no more than 1 to 2 mm thick. Doses have ranged from 2000 to 45,000 cGy per site. A reasonable dose in most cases is probably 100 cGy. Nonrecurrence rates using $\gamma$ probes.
for ocular squamous cell carcinoma have ranged from 87.5% to 89% over 1 to 6 years of follow-up.\(^5\)\(^,\)\(^23\) Radiation-induced keratopathy has been reported in one horse after \(^{90}\)Sr irradiation of a limbal squamous cell carcinoma.\(^19\)

More extensive conjunctival squamous cell carcinomas can be irradiated with interstitial implant radiotherapy. This is particularly true for squamous cell carcinomas that cannot reliably be debulked to a thickness of less than 2 mm. Various modalities of interstitial therapy have been used for ocular and periocular squamous cell carcinoma, including radon-222, gold-198, iridium-192, cobalt-60, cesium-137, and iodine-125.\(^5\)\(^,\)\(^20\)\^-\(^23\) Minimal total doses of 3600 to 10,000 cGy have been used, with reported nonrecurrence rates of 60% to 87% with follow-up periods between 3 months and 2 years in different studies.\(^5\)\(^,\)\(^20\)\^-\(^23\) Implants are placed in periocular eyelid skin after debulking the tumor and performing a complete, temporary tarsorrhaphy (Fig. 57-7). The author uses a dose of 5000 to 7000 cGy over 5 to 7 days.

**Orbital exenteration and radiation therapy**

Invasive conjunctival squamous cell carcinoma should be treated by orbital exenteration and radiation with interstitial implant radiotherapy. Implants are inserted into the eyelid skin after it is closed over the exenterated orbit.

**Cryotherapy**

Cryotherapy can be used for conjunctival squamous cell carcinoma. Cure rates of 66% to 97% have been reported in cattle and horses, although the period of follow-up has not always been well defined. Care must be taken to limit the extent of freezing if only the conjunctiva is involved. A polystyrene cup can be used to shield the cornea during freezing, and petrolatum ointment can be applied to the cornea and ocular adnexa. Use of a probe rather than a spray limits the effects on surrounding tissues (see Chapter 15). A thermocouple should be used to monitor tissue temperatures during freezing to ensure adequate therapy.\(^24\) The cryogens most frequently used are liquid nitrogen and CO\(_2\). The lesion is frozen rapidly to \(-20^\circ\) to \(-30^\circ\) C and allowed to thaw slowly. The tissue is then frozen again rapidly.\(^24\)\^-\(^27\)

**Hyperthermia**

Radiofrequency hyperthermia has been used for conjunctival squamous cell carcinomas in horses and cattle.\(^5\)\(^,\)\(^28\)\^-\(^30\) Tumors should be debulked if thicker than 3 mm or wider than 25 mm.\(^28\)\^-\(^29\) Electric current of 2 MHz is passed between two electrodes applied to the tissue. The tissue temperature is raised to 50\(^\circ\) C for 30 seconds.\(^29\)

**Other Tumors**

Other reported neoplasms that involve the conjunctiva in the horse are angiosarcomas,\(^9\)\(^,\)\(^31\)\^-\(^32\) hemangiosarcomas,\(^13\)\(^,\)\(^32\)\^-\(^33\) lymphosarcomas,\(^32\)\(^,\)\(^34\) and melanomas.\(^32\)\^-\(^37\) Angiosarcomas arise in the conjunctiva of aging horses, are locally invasive, and eventually metastasize to regional lymph nodes. The prognosis for angiosarcomas is unfavorable.\(^8\)

Surgical excision or reduction of tumor size is the most appropriate means of both diagnosis and therapy. When the neoplasia has extensively involved the conjunctiva and globe, enucleation is the most appropriate therapy. The orbit should be exenterated if there is any doubt as to the extent of local invasion. Depending on the type of tumor, interstitial implant radiotherapy may be indicated.

Conjunctival melanomas are less common than intraocular melanomas in the horse. In two case reports, they responded to either local excision or excision with combined cryotherapy.\(^55\)\^-\(^36\) In another case, repeated local excision and cryotherapy was unsuccessful in preventing local invasion of the melanoma into the cornea and sclera. Exenteration of the orbit was effective in treating the disease.\(^35\)

**Conjunctival Pseudotumors**

Unilateral raised pink smooth masses involving the bulbar conjunctiva or the third-eyelid conjunctiva have been reported in horses 5 to 8 years of age. These may be flat and diffuse or focal and nodular in appearance. Histologically, these contain large numbers of lymphocytes and may represent an immune-mediated disease (similar to fibrous histiocytoma or nodular fasciitis in dogs). These masses can usually be treated effectively by surgical excision or debulking and/or topical or intralesional use of anti-inflammatory drugs (corticosteroids).\(^38\)

**Conjunctival Papillary Endothelial Hyperplasia**

A single report exists of conjunctival papillary endothelial hyperplasia (IPEH) affecting the perilimbal conjunctiva of a horse. By its appearance, the lobulated, raised, red mass could be mistaken for a malignant vascular tumor. Surgical excision of the mass and adjacent bulbar conjunctiva was curative.\(^39\)

**Aftercare**

Postoperative care of corneal ulceration treated with a conjunctival flap is discussed in Chapter 60. In all cases when conjunctival flaps are deemed necessary for therapy of corneal ulceration, the author recommends a subpalpebral lavage as the most effective method of applying medications (see Chapter 55).
Postoperative therapy for conjunctival neoplasia should include antibacterial agents and a mydriatic/cycloplegic drug if uveitis is present.

Complications

Failure to close the conjunctiva over an area of sclera from which a flap has been dissected may result in postoperative infection, although clinical experience indicates that this is a rare occurrence. Exposed sclera in the horse appears to heal with more vascularization and granulation tissue formation than in small animals. If topical antibacterial drugs are used after surgery, this should not be a problem.

Radiation therapy may result in injury to other ocular structures in isolated cases, and it definitely occurs if careful attention is not given to the dose of radiation being delivered. Complications of interstitial radiation therapy have included temporary corneal opacification and edema, epithelial desquamation, and necrosis. The complications are rarely severe enough to warrant enucleation.20,22,23

REFERENCES

The third eyelid (membrana nictitans, nictitating membrane, or plica semilunaris conjunctivae) is situated inferomedially in the anterior part of the orbit between the eyelids and the globe. The structure is a T-shaped to irregularly-shaped piece of elastic cartilage that is covered by a fold of conjunctiva reflected from both the palpebral and bulbar conjunctiva. The cartilage is curved to conform to the anterior curvature of the globe. The top of the T ends a few millimeters behind and supports the free, often pigmented, margin of the third eyelid. The gland of the third eyelid, serous in nature in horses, surrounds the base of the cartilage. In dogs, the gland secretes into the conjunctival sac via ductules on the bulbar surface of the third eyelid, and the same is presumably true in the horse. Some horses may also have glandular tissue on the convex (palpebral) side of the third eyelid1,2 (Fig. 58-1).

The surfaces and apex of the third eyelid are covered by stratified squamous epithelium, which becomes columnar epithelium containing mucus-secreting goblet cells and intraepithelial glands at the third-eyelid base.3 A substantia propria of loose connective tissue, which is associated with blood vessels, is located beneath the epithelium. Lymphatic nodules are clustered in the substantia propria of the bulbar surface of the third eyelid. The third eyelid receives blood vessels from the malar artery, a branch of the internal maxillary artery. Large blood vessels pass through the lymphoid follicles on the bulbar surface of the third eyelid. Sensory innervation is derived from the trigeminal nerve.1 Anesthesia of the conjunctival surface can be achieved with topical application of proparacaine hydrochloride. For anesthesia of the deeper structures, local infiltration of the base of the third eyelid is required.

In horses, movement of the third eyelid occurs passively, depending on retraction of the globe into the orbit by the retractor bulbi muscles, which pushes orbital fat and the third eyelid forward. The third eyelid is capable of covering most of the cornea when protracted.1,2

PATHOPHYSIOLOGY

The third eyelid may protrude unilaterally from its normal position whenever there is an orbital space-occupying lesion present. A mass located inferomedially outside the cone of extraocular muscles is especially likely to cause third eyelid protrusion. The third eyelid also protrudes when the eye is retracted because of ocular pain (e.g., in uveitis or corneal ulceration) or if the globe is smaller than normal (either a congenital microphthalmia or an acquired phthisis bulbi secondary to uveitis or glaucoma). Occasionally, the third eyelid may protrude in horses with Horner’s syndrome.4 Bilateral protrusion may occur in some systemic diseases with infiltration of the orbit (lymphosarcoma) or in debilitated animals with loss of orbital fat and recession of the globe in the orbit. In horses with tetanus, the third eyelid may be visible and rapidly move across the eye in response to stimuli to the head.5,6

In cases of conjunctivitis, the third-eyelid conjunctiva is involved with the palpebral and bulbar conjunctiva. Hyperplasia of the lymphoid follicles on the bulbar surface of the third eyelids is often obvious, although lymphoid tissue on other conjunctival surfaces also may be enlarged.

DIAGNOSTIC PROCEDURES

The third eyelid should be examined carefully in any horse with conjunctivitis or keratitis. The anterior surface can be examined by pressing the globe posteriorly into the orbit with digital pressure applied through the upper eyelid. The third eyelid will passively protrude, enabling examination of its anterior surface. To examine the folds of conjunctiva at the base of the anterior surface or to examine the bulbar surface of the third eyelid, proparacaine hydrochloride is applied to the eye and the cross-bar of the T cartilage is grasped with serrated forceps. The third eyelid can then be drawn from the conjunctival sac and reflected anteriorly to expose the bulbar surface. Examination behind the third eyelid is important in locating foreign bodies and conjunctival parasites, including Thelazia. The margin of the eyelid
should not be held with forceps because it will tear easily if the horse pulls away during examination. The eyelid can also be palpated for masses after application of topical anesthetic.

Conjunctival lesions can be cultured and scrapings taken for cytology the same way as for other conjunctival lesions. Masses on the conjunctiva should undergo biopsy for histopathologic examination. This can usually be achieved with an auriculopalpebral nerve block and topical anesthesia alone. For potentially deep masses, local infiltration of anesthetic should supplement topical anesthesia.

For surgery on the third eyelid in a sedated standing animal, topical proparacaine hydrochloride is applied to the eye. Local anesthesia is achieved by lacrimal and zygomatic nerve blocks. The third eyelid is elevated and 5 to 10 mL of 2% Xylocaine hydrochloride is injected along the base.

**SURGICAL TECHNIQUES**

**Third Eyelid Flap**

The third eyelid is often used as a flap to cover lesions of the cornea and, in particular, corneal ulcers. The rationale for using a third-eyelid flap is as follows: the flap, when placed correctly, provides physical protection for the cornea and may bring blood supply (from the conjunctiva covering the third eyelid) into close apposition with the corneal lesion and promote healing. No controlled study has been performed in any species to determine whether third-eyelid flaps promote healing of corneal lesions. It is possible that corneal ulcers that heal with a third-eyelid flap in place would have healed as well with medical therapy alone. Potential disadvantages of the third-eyelid flap include the following:

1. A third-eyelid flap applied over the cornea obscures any view of the cornea, making it difficult to evaluate improvement or deterioration of the corneal lesion (unless sutures are tied in such a way as to allow the flap to be lowered periodically).
2. If poorly applied, the third-eyelid flap may apply pressure to the cornea and, in cases of deep corneal ulceration, may actually promote perforation of the cornea.
3. The third-eyelid flap may prevent topically applied medications from reaching the corneal lesion in adequate concentrations to combat infection.

When deep stromal corneal ulcers, melting ulcers, or descemetoceles are present, conjunctival flaps or corneal grafts (including the corneoscleral transposition) are better means of treating the problem. These techniques allow the eye to be easily examined and effectively medicated; they provide a good blood supply to the cornea, and they may offer some support for a thin area of the cornea.

Third-eyelid flaps may be used in horses for superficial corneal ulcers that cannot be medicated by the owner. The flap is placed under general or local anesthesia with sedation. Three or four horizontal mattress sutures of non-absorbable 2-0 to 3-0 material are used. The sutures are inserted from the skin into the upper conjunctival fornix. The sutures pass through the palpebral surface of the third eyelid 4 to 5 mm behind its free margin. The cartilage of the third eyelid may be encircled by the suture but probably should not be penetrated by the needle or the suture. The suture is again passed through the upper eyelid via the fornix. Stents of polyethylene tubing may be used over the upper eyelid to distribute pressure. Tension on the third-eyelid flap is relieved by performing a temporary tarsorrhaphy at the same time. It is recommended that, whenever possible, the third-eyelid flap be placed along with a subpalpebral lavage system (see Chapter 55) to medicate the eye effectively. The sutures of the flap may be tied with a bow to allow lowering of the flap and evaluation of the progress of corneal healing or deterioration.

**Excision**

Excision of the third eyelid can be performed either under general anesthesia or in the standing animal with adequate local anesthesia and analgesia. The latter requires sedation with xylazine or detomidine; auriculopalpebral, infratrochlear, and zygomatic nerve blocks; and infiltration of local anesthetic at the base of the third eyelid (Fig. 58-2). Topical proparacaine hydrochloride should be applied to the conjunctiva.

The third eyelid is grasped at either end of the T of the cartilage with Allis tissue forceps or towel clamps and elevated from the fornix. Two hemostats are clamped across the base of the third eyelid as far from the visible margins of the tumor as possible. The hemostats form a V with the tip at the base of the eyelid and should be clamped below the cartilage. The distal part of the third eyelid is excised with either a scalpel or scissors, taking care to include the cartilage and third-eyelid gland. The hemostats are left in place for a few minutes. Usually there is no need to suture the cut conjunctival edges, although this can be done with 6-0 absorbable suture if prolapse of orbital fat is a problem. The excised tissue should be submitted for histopathologic examination, with the request that the borders of the excised tissue be examined.

**SURGICAL DISORDERS**

**Lacerations**

Lacerations of the third eyelid may involve only the conjunctiva or the cartilage. Even if the cartilage is torn, the goal of repair is to restore apposition of the edges of the conjunctiva and, in particular, to repair the third-eyelid margin.

Sutures should start at the third-eyelid margin and progress toward the base for accurate apposition of the margin. Absorbable 6-0 to 8-0 sutures are used with an atraumatic needle. Sutures should emerge on the palpebral surface of the third eyelid, and knots should be buried. Care must be taken not to allow suture material to emerge through the bulbar surface and abrade the cornea. The cartilage should be completely covered by conjunctiva to avoid corneal damage by exposed cartilage.

**Neoplasia**

**Squamous Cell Carcinoma**

The third eyelid is the most common site of ocular squamous cell carcinoma in the horse. Details of the disease affecting the equine eye are found in Chapter 57.
The tumor affecting the third eyelid initially appears as an area of hyperemia. The lesion becomes raised and occasionally has a papillomatous appearance (Fig. 58-3). The diagnosis is confirmed by impression smears or biopsy.

Treatment of squamous cell carcinoma of the third eyelid usually requires removal of the entire structure. Small lesions may be excised from the conjunctival surface while sparing the third eyelid as a whole; however, histopathology should be used to ensure that margins of the excised tissues are free of tumor tissue. If the margins are not clear of tumor, the third eyelid should be completely removed. If the tumor appears extensive or there is any doubt as to how much of the conjunctival surface is involved, complete excision of the eyelid is recommended. Horses rarely appear to have any significant problems after nictitans removal, and this is definitely a better option than tumor extension into tissues around the third eyelid.

Alternatively, excision of the visible tumor from the conjunctiva can be followed by γ-irradiation or cryotherapy over and adjacent to the biopsy site to provide an added safeguard against tumor recurrence. Radiofrequency hyperthermia has also been used with some success to treat squamous cell carcinoma of the third eyelid in horses.13,18

In extensive cases of squamous cell carcinoma involving the third eyelid, the nictitating membrane should be excised and other therapies used in the surrounding tissues. In view of the potential local spread of tumor tissue in the distomedial fornix, cryosurgery may be difficult to achieve practically. Radiotherapy is a valuable technique for treatment of squamous cell carcinoma in this relatively inaccessible site.13,19 The author has used γ-irradiation at this site by inserting radiation sources in the eyelids at the medial canthus. Options for irradiation of the conjunctiva are discussed in Chapter 57.
Other Tumors
Other reported third-eyelid tumors in horses include sebaceous adenocarcinomas, squamous papillomas, basal cell tumor, and lymphosarcomas. Localized lesions are best treated by excision for histopathology coupled with either cryosurgery or radiotherapy.

Aftercare
Horses that have undergone third-eyelid surgery should receive topical antibacterial agents BID or TID. Parenteral antibiotics are recommended after excision of the third eyelid. If sutures have been used in or around the third eyelid, the cornea should be observed closely for any evidence of suture irritation.

Complications
Protrusion of the cartilage of the third eyelid after local excision of neoplasms could result in corneal irritation. The cartilage should be removed completely when the third eyelid is excised. Although no cases of chondrosarcoma affecting the third-eyelid cartilage have been reported, the propensity of the horse to develop tumors of damaged cartilage at other sites should promote caution when performing surgery on the third eyelid.

Herniation of orbital fat after excision of the third eyelid may be prevented by suturing the inferomedial conjunctival defect, although in this author’s experience this is rarely necessary. Hemorrhage from conjunctival or orbital vessels is rarely a problem when removing the third eyelid and rarely justifies attempts at hemostasis. If this is a concern, cautery can be applied to the stump of conjunctiva when hemostats are removed.

ANATOMY

Tears are produced by the lacrimal gland, located in the orbit between the supraorbital process and the superotemporal aspect of the globe, separated from the globe by the periorbita. There are 12 to 16 excretory ducts opening into the temporal conjunctival sac near the fornix. Tears are also produced by the nictitating gland found at the base of the nictitans membrane.

The lacrimal puncta drain tears from the conjunctival sac. The two puncta are located on the conjunctival surface of the upper and lower eyelid, near the free edge, about 8 mm from the medial canthus (Fig. 59-1). Each is a small (2-mm) slit-like opening that empties into a canaliculus, and the canaliculi converge to form the lacrimal sac. The lacrimal sac sits in the funnel-like opening of the bony lacrimal canal and leads into the (common) nasolacrimal duct, which passes along the outer wall of the frontal sinus and nasal cavity.1 Proximally, the duct is enclosed in bone for 7 to 8 cm; distally, it lies in the lacrimal groove of the maxilla, covered by cartilage. Further distally, it is covered only by the mucous membrane of the middle meatus.1,2 The external opening of the nasolacrimal duct, the distal punctum, is situated on the floor of the nasal cavity, about 5 cm into the nostril. The opening is seen at the junction of the skin and the mucous membrane (Fig. 59-2). Accessory openings may be present farther back. 1 In mules, the distal punctum opens on the lateral part of the floor or the lateral wall of the nostril.1

The precorneal tear film, which is essential for the maintenance of a transparent cornea and healthy conjunctivae, is composed of three layers. The outer layer consists of an oily secretion produced by the meibomian or tarsal glands. This layer decreases evaporation of the aqueous layer and prevents tear overflow. The middle layer is the aqueous layer derived from the lacrimal and nictitating glands. This layer provides lubrication for the lids, flushes foreign material from the conjunctival sac, and allows atmospheric oxygen to be transferred to the cornea. Antibodies and leukocytes can be found in this layer. The deep layer consists of mucin secreted by conjunctival goblet cells. Mucous threads allow lubrication and coat foreign bodies to protect the cornea. Mucin contributes stability to the precorneal tear film, as does the outer layer, and furnishes an attachment of tear film to cornea and conjunctiva. Mucin on the surface of corneal epithelial cells acts to reduce surface tension. In the aqueous phase, mucin acts to smooth and spread the tear film.3

PATHOPHYSIOLOGY

Abnormalities of the lacrimal and nasolacrimal systems include insufficient production of the precorneal tear film, which can include both quantitative and qualitative abnormalities, and insufficient drainage of tears. Insufficient production of the precorneal tear film is uncommon in horses.

Abnormalities of drainage are seen as an overflow of tears known as epiphora. This must be distinguished from an increased production of tears that overwhelms the capacity of the normal nasolacrimal duct.

DIAGNOSTIC PROCEDURES

Tear Production

Abnormalities of the oily or mucous layers of the precorneal tear film have not been described in horses, whereas abnormalities of the aqueous layer have been described4,5 but are
uncommon. This is in contrast to dogs, where low tear production causing keratoconjunctivitis sicca is common.

Aqueous tear production is measured using Schirmer Tear Test strips (Cooper Vision, San German, Puerto Rico). Commercially available Schirmer Tear Test strips measuring 5x35 mm have been used to measure tear values in horses. In 50 normal horses, the mean wetting was 24.8 mm in 60 seconds. Schirmer Tear Test strips can also be made by cutting Whatman no. 41 filter paper into 5x40 mm strips and placing a notch 5 mm from one end.

Culture

The nasolacrimal system is cultured, when necessary, by retrograde flushing of the nasolacrimal duct. When purulent material is seen at a punctum, a Culturette (Becton Dickinson and Co., Cockeysville, Md) is used to harvest this material. Aerobic and anaerobic cultures should be performed.

Dye Passage

Patency of the nasolacrimal duct is most easily assessed by instilling fluorescein into the conjunctival cul-de-sac and examining for its appearance at the distal punctum. Either a moistened fluorescein strip is touched to the bulbar conjunctiva or a freshly made fluorescein solution is instilled into the conjunctival sac. Fluorescein should be seen at the distal punctum within a few minutes.

Nasolacrimal Duct Irrigation

If fluorescein dye does not traverse the nasolacrimal duct, flushing of the duct should be performed. The horse is restrained, the distal punctum identified, and a catheter passed up the nasolacrimal duct (see Fig. 59-2). Occasionally, the tip of the catheter hits a blind end several centimeters from the punctum, corresponding to an area of the duct compressed by the medial accessory cartilage. If the catheter is directed laterally, this can be avoided. Six to 10 mL of saline or irrigating solution (Dacriose, Iolab, Claremont, Calif) are flushed into the catheter while holding a finger over the punctum to prevent backflow. An open-ended tomcat catheter or a no. 8 polyethylene catheter is ideal for this procedure. If the punctum cannot be located, the nasolacrimal duct can be flushed from one of the proximal puncta. The auriculopalpebral nerve should be blocked and the conjunctiva anesthetized with a topical ophthalmic anesthetic such as proparacaine hydrochloride. A 20-gauge nasolacrimal cannula can be used to cannulate either the upper or the lower punctum, and saline or an irrigating solution may be used to flush the duct.

Dacryocystorhinography

If the nasolacrimal duct cannot be flushed, dacryocystorhinography is the best way to determine the site of the obstruction. Dacryocystorhinography refers to the radiographic study of the nasolacrimal duct using a positive contrast medium. The horse must be under general anesthesia to perform this study. The nasolacrimal duct is cannulated at the eyelid, and 2 to 5 mL of a radio-opaque contrast material (ethiodized poppy seed oil, Ethiodol, or propyliodone oil, Dionosil Oily) is injected. Care is taken to avoid getting the oil into the conjunctival cul-de-sac. Lateral and dorsoventral or oblique radiographic views are taken. A normal dacryocystorhinogram is shown in Figure 59-3. Computed tomography and magnetic resonance imaging are potentially useful in diagnosing nasolacrimal duct problems.
SUROICAL DISORDERS

Punctal Atresia

The most common congenital nasolacrimal disorder is atresia of the distal punctum. Clinical signs include persistent epiphora or mucopurulent discharge, usually noticed from birth on, although occasional horses do not show severe clinical signs until they are 1 to 2 years old. In most cases, the duct opening is covered by only a thin layer of mucosa.

The duct can be filled with saline after cannulating a proximal punctum and the mucosa incised over the saline bleb with a scalpel blade. This can usually be performed in a standing sedated foal. Alternatively, it may be easier to identify the end of the duct by passing a catheter through a proximal punctum and incising over the tip of the catheter. A no. 6 cardiac catheter with a guide wire is often effective for this purpose. After the nasolacrimal duct is opened, the guide wire is removed and the catheter sutured to the face near the eyelids and to the floor of the nostril (Fig. 59-4). Alternatively, an incision can be made in the lateral wall of the nostril, and the catheter can be pulled through the incision and sutured to the chin or the face. The catheter should be left in place for 2 weeks.

Horses may also suffer from atresia of the upper or lower eyelid punctum. The absence of the punctum can be seen with magnification, or a bleb can be raised when the duct is cannulated from the nose and saline is instilled. In this case, the duct is easily opened with a scalpel blade. Fastening a stent is ideal, but ducts sometimes heal open without a stent. If the imperforate punctum cannot be identified, dacryocystorhinography should be performed to delineate the existing nasolacrimal duct. The surgical approach can then be determined.

Lacerations

Lacerations of the nasolacrimal system, usually seen at or near the eyelids and possibly involving the nasolacrimal puncta, require expert repair. The lacerated canaliculus must be cannulated to identify the severed ends and to allow primary closure to maintain patency (Fig. 59-5). This can be achieved by passing a Worst pigtail probe through the unaffected punctum and rotating the probe out of the severed canaliculus. A fine suture material (e.g., 6-0 silk) is threaded into the probe, and the probe is withdrawn, placing the suture from the laceration through the normal punctum. The probe is then passed through the punctum of the lacerated canaliculus. The suture is threaded into the probe, and the probe is withdrawn, drawing the suture through the second punctum. A tapered silicone tubing is tied to the suture and drawn into one punctum, through the canaliculi, and out through the second punctum. The canaliculus and the laceration are sutured with 6-0 silk or nylon. The tube is sutured to itself and left in place for several weeks to maintain patency as the canaliculus heals.

Alternatively, a nasolacrimal duct cannulation can be performed if a Worst probe cannot be passed successfully. Monofilament nylon (2-0) can be passed from the distal nasal punctum retrograde through the nasolacrimal duct to exit the lacerated canaliculus. The Worst probe is used to draw the suture through the proximal portion of the severed canaliculus. The suture is tied to fine silicone tubing, and the tubing is drawn normograde through the canaliculus and the nasolacrimal duct. The tubing is sutured to the skin at the puncta and at the nasolacrimal orifice.

Dacryocystitis

Dacryocystitis refers to inflammation of the nasolacrimal duct and is seen infrequently in horses. Clinical signs include chronic conjunctivitis, with mucopurulent to purulent discharge from the eye. Purulent material can be expressed at the proximal punctum with manipulation or flushing. Occasionally, foreign bodies can be irrigated from the duct and are the likely cause of the inflammation, but most cases do not have a determinable etiology.

Treatment of dacryocystitis in horses is similar to that in other species. A culture is taken of the purulent material expressed or flushed from the nasolacrimal punctum. Topical antibiotics may be applied, but appropriate systemic
antibiotics often must be used to effect a cure. Additionally, the distal portion of the nasolacrimal duct can be cannulated, the cannula sutured into place (see earlier discussion), and an appropriate antibiotic solution flushed through the duct daily.

Blockage of the Nasolacrimal Duct

Acquired blockage of the nasolacrimal duct is seen commonly in the horse. Frequently, epiphora is the only clinical sign, although with chronicity a mucopurulent discharge may be seen.

Patency can be checked with fluorescein dye, and if the duct is not patent, it is flushed from the distal punctum. If flushing is unsuccessful, dacryocystorhinography should be performed.

Causes of acquired nasolacrimal duct blockage include trauma, foreign bodies, and swelling of the duct wall because of inflammation. Diseases of adjoining structures may cause blockage or stenosis of the duct. These include chronic rhinitis or sinusitis, neoplasms of the nasal passages or sinuses, and osteomyelitis from actinomycosis or periodontitis.

Canaliculorhinostomy has been described in the horse for treating an acquired blockage of the nasolacrimal duct. This surgery created a fistula running from the lower lid canaliculus to the rostral maxillary sinus. Conjunctivorhinostomy has been described in dogs and cats as another treatment for blocked nasolacrimal ducts. A permanent mucous membrane–lined fistula is created between the inferonasal conjunctival sac and the nasal cavity. This procedure may have applicability in horses but has not been described in this species.

Keratoconjunctivitis Sicca

Keratoconjunctivitis sicca refers to the abnormal drying of the cornea and conjunctiva caused by a decrease in the aqueous phase of the precorneal tear film. Clinical signs in horses include a chronic tenacious mucopurulent discharge and chronic corneal ulceration. Causes of keratoconjunctivitis sicca described in horses include eosinophilic dacryoadenitis, locoweed poisoning, and trauma to the nerves that innervate the gland. The lacrimal gland is innervated by parasympathetic fibers of the facial nerve (cranial nerve VII). Damage to cranial nerve VII may cause additional clinical signs of ipsilateral ear droop, ptosis, and deviation of the muzzle to the contralateral side. Sulfonamide toxicity has been described in dogs to induce keratoconjunctivitis sicca, and it is theoretically possible that chronic sulfonamide therapy in horses could do the same.

Parotid duct transposition has been described as a treatment for keratoconjunctivitis sicca in horses. This procedure involves moving the parotid salivary duct to the conjunctival sac of the affected eye. Saliva is subsequently continuously secreted onto the eye. Although it is not a perfect tear substitute, saliva is a reasonable alternative to tears and is usually effective in moistening the ocular surface. Topical cyclosporine has also been used successfully to treat keratoconjunctivitis sicca in a horse.

CHAPTER 60

Cornea and Sclera
Mark P. Nasisse
Vivian E. Jamieson
Dennis E. Brooks

Of the domestic large-animal species, the horse demonstrates the greatest predisposition toward ocular diseases requiring surgical therapy. Because of the relatively large globe size, the normal protrusion of the corneal surface, and the environment in which horses exist, ocular trauma is common.1,3 The direct effects of ocular trauma or the secondary complications mediated by infectious agents often mandate surgical intervention. The tendency of aged horses to develop limbal neoplasms provides further indication for surgery of the corneal and scleral tissues. Successful preservation of vision in such cases depends on the ability of the equine surgeon to apply the principles of corneal and scleral surgery.

ANATOMY

The cornea forms the anterior one fourth of the outer fibrous tunic of the globe and is continuous with the sclera.4,5 It is horizontally elliptical, being slightly more narrow laterally. The diameter is greater horizontally than vertically (32 to 38 and 26 to 28 mm, respectively), and the radius of curvature is approximately 17 mm. As in other animal species, the cornea is the major refractive surface of the globe (refractive index = 1.37). The thickness of the equine cornea varies from 0.56 mm centrally to 1 mm peripherally.

Histologically, the cornea consists of four layers (Fig. 60-1). The anterior layer is nonkeratinized, stratified squamous epithelium, approximately 10 to 15 cell layers thick, with a thin basement membrane. The substantia propria (stroma) makes up 90% of the corneal thickness and is composed of regularly arranged collagen lamellae, which are separated by a ground substance of mucopolysaccharides that vary according to corneal region, and

Figure 60-1. Photomicrograph of normal equine cornea. The four layers include the epithelium (a), the stroma (b), Descemet’s membrane (c), and the endothelium (arrow) (d). (H & E, ×170.)

specialized fibrocytes (keratocytes). A rich supply of sensory nerves, originating from the ophthalmic branch of the trigeminal nerve, extends radially into the midstroma. Nerves branch extensively to terminate as a plexus of free nerve endings in the superficial stroma and epithelial layer. Descemet’s membrane is a tough, elastic basement membrane secreted by the deepest layer of the cornea, the posterior epithelium (endothelium). It is 21 microns thick in the adult horse. The endothelium is a monolayer of hexagonally shaped epithelial cells.

A pigmented limbus marks the transition between the cornea and the sclera. A scleral “shelf,” which is wider dorsally and ventrally, projects into the superficial corneal stroma at the limbus and obscures the view of the insertion of the pectinate ligaments onto Descemet’s membrane. The sclera is thickest anterior to the equator (1.3 to 3 mm) and thinnest at the insertion of the extraocular muscles. Histologically, the sclera is composed of a superficial vascular layer called the episclera, a thicker central layer called the stroma, and an innermost pigmented layer called the lamina fusca. The random arrangement of the sclera’s collagen bundles and the relative lack of corneal hydration account for its lack of transparency.

PATHOPHYSIOLOGY
Uncomplicated Corneal Wounds

The process by which corneal wounds heal varies considerably with the size, location, and depth of the injury. After an acute epithelial wound that is uncomplicated by secondary infection, the healing process begins with migration of adjacent epithelial cells. Cells of the epithelium’s basal layer send out cytoplasmic processes within 1 hour of the injury as they prepare to slide over the defect. Within several days of the injury, the same cells increase their mitotic activity as they begin regenerating new epithelium. Complete re-epithelialization of a 12-mm defect may occur in as little as 7 days (0.6 mm/day). Rapid healing of a noninfected superficial ulcer is often followed by a lag phase of slow epithelial movement. Healing of defects involving the epithelial basement membrane takes longer, because hemidesmosomes, which attach the basal epithelial cells to the basement membrane, require several weeks to re-form.

Healing of stromal wounds is considerably more complex and time consuming. In a corneal laceration, the process begins with fibrin filling the stromal defect. Leukocytes, whose principal source is the tear film, are quick to migrate to the lesion (usually within several hours) to serve phagocytic and nutritional functions in the damaged tissue. At the same time, epithelial cells bridge the defect as previously described. Keratocytes adjacent to the wound are eventually stimulated to differentiate into fibroblasts and begin secreting collagen. Once the stromal defect is filled, the slow process of wound remodeling, often requiring weeks to months, ensues as stromal cellularity decreases, fibroblasts cease metabolic activity, and collagen fibrils reorient in a parallel direction. Because the perfect lamellar arrangement of the original collagen fibrils can never be duplicated, healing of stromal wounds invariably results in scar formation, the extent of which is commensurate with the degree of stromal damage.

Complicated Corneal and Scleral Wounds

When factors obstruct restoration of corneal or scleral structural integrity or prevent restoration of functional vision after healing of the fibrous tunic is complete, wounds are referred to as “complicated.” The most common complicating factor in corneal wounds is the establishment of secondary microbial infection. In the normal equine conjunctival sac, gram-positive bacteria predominate. In several studies, Corynebacterium species have been reported to be most frequently encountered; however, β-hemolytic streptococci, staphylococci, and bacilli are also commonly isolated. Even Pseudomonas, well known for corneal pathogenicity, is occasionally isolated from normal conjunctiva. Fungal hyphae have been isolated from the conjunctiva of 95% of normal horses. Those recovered most commonly were Aspergillus and Penicillium. Studies reporting microbial isolates from diseased eyes indicate that gram-negative organisms, particularly Pseudomonas, Enterobacter, and Acinetobacter, are most pathogenic. Other reported pathogenic species include streptococci, especially the devastating β-hemolytic streptococcal species, Corynebacterium, staphylococci, and Salmonella. Aspergillus is the most commonly reported fungal pathogen, followed by Fusarium. Other fungi, such as Penicillium, Phycomycetes, Pseudallescheria boydii, and Cylindrocarpon destructans, have also been described.

The ubiquitous exposure of the equine cornea to microorganisms demonstrates the importance of some predisposing event in the establishment of infection. That event, in most instances, is traumatic disruption of corneal epithelium; bacteria and fungi that are not normally pathogenic become so when access to the corneal stroma is provided. The chronic use of topical antibiotics, which may shift the resident flora from being predominantly gram positive to gram negative, may also play a role. Replication of microorganisms that have established a foothold in the damaged corneal tissue has several significant adverse effects. First, the production of collagenolytic enzymes (proteases) from microorganisms and degenerating corneal cells precipitates the clinical phenomenon of corneal melting (Fig. 60-2). Melting may be associated with no infection in foals, but it tends to be more severe with bacterial than fungal infection. In cases of rapidly melting corneal ulceration, perforation can occur in as little as 48 hours. Fungi, in contrast to bacteria (which remain confined to the corneal surface), are capable of migrating through the corneal stroma. Tear film instability may precede fungal invasion of the equine corneal epithelium. Endophthalmitis, therefore, is a potential and significant complication of keratomycosis. Even if organisms have not gained access to the anterior chamber, corneal sepsis provides a strong stimulus for secondary intraocular changes. Release of chemotactic factors and toxins may cause the formation of sterile hypopyon (accumulation of inflammatory cells in the anterior chamber). Breakdown of the blood ocular barrier, evidenced by aqueous flare (increased protein) and miosis, is mediated by stimulation of the sensory corneal nerves (branches of the ophthalmic division of cranial nerve V) that results in antidromic release of substance P and other polypeptides to the iris.

In the event that a globe becomes perforated, whether by sharp injury or perforation of an infected corneal ulcer,
Fibrous amounts of fibrin spill into the aqueous humor. Fibrin normally has a protective effect by plugging the corneal wound, often with the help of entrapped uveal tissue. In the event this corneal plug is ineffective and aqueous humor continues to leak from the wound, a persistent state of hypotony follows that may result in uveal atrophy and, eventually, phthisis bulbi. Ciliary atrophy and phthisis bulbi also may occur as the direct effects of ocular trauma.

**DIAGNOSTIC PROCEDURES**

**Ophthalmic Examination**

The ophthalmic examination should proceed in a systematic anterior-to-posterior fashion. The eyelids are first scrutinized with magnification for foreign bodies, neoplasms, or traumatic lesions. The most important abnormalities to be considered when examining the cornea are edema, vascularization, cellular infiltrates, neoplastic growths, foreign bodies, and alterations in structural integrity (Fig. 60-3, and see Fig. 60-2). Structural integrity is assessed first with the application of fluorescein (Fluorets ophthalmic strips) to detect disruptions in the epithelial barrier. Fluorescein should be applied at full strength and not diluted. It is important that excess stain be thoroughly rinsed from the eye to avoid misinterpreting stain pooled in an epithelialized stromal defect as an active ulcer. Rose bengal stain should be applied to detect tear film instability in all horses with painful eyes. The hydrophilic rose bengal dye stains epithelial cells or stains the stroma in the absence of the tear mucin layer or epithelial cells, respectively. Perforation of the cornea can be difficult to detect, but it is usually indicated by one of several clinical signs. Because uveal prolapse consistently accompanies the leakage of aqueous humor, the presence of pigmented tissue in or adjacent to the corneal wound is indicative of perforation (Fig. 60-4). Organized fibrin is usually present, often in large quantities, and frequently obscures the corneal defect (Fig. 60-5). In such cases, it becomes necessary to rely on other clinical signs. By viewing the anterior chamber obliquely from the limbus, it is possible to determine if the iris is displaced forward. Applanation tonometry is useful for documenting extremely low intraocular pressure (less than 10 mm Hg), which is suggestive of aqueous humor leakage. Finally, Seidel's test may be used to confirm leakage of aqueous humor: after the tear film is heavily saturated with fluorescein stain, the area of the suspected perforation is examined under magnification with a cobalt blue light for a change in color, indicating a mixture of aqueous humor with the tear film.

Examination of the anterior chamber should include a deliberate effort to detect increased protein (flare), inflammatory cells (hypopyon), and blood (hyphema). As men-

**Figure 60-2.** Melting corneal ulcer in a horse. Corneal infection by *Pseudomonas aeruginosa* has resulted in extensive liquefaction of the corneal collagen.

**Figure 60-3.** Typical appearance of keratomycosis in a horse. The cornea is extensively edematous. There is deep vascularization; and fungus-infected tissue is visible on the corneal surface.

**Figure 60-4.** A globe rupture by blunt trauma. The cornea has been ruptured from the medial to the lateral limbus, and massive uveal tissue protrudes from the wound.
tioned previously, the presence of hypopyon in the absence of corneal perforation may not suggest a poor prognosis. If its presence is secondary to bacterial keratitis, the hypopyon is sterile and will readily resolve with proper antimicrobial therapy. In fungal infections, because the organisms can migrate through Descemet’s membrane, the presence of hypopyon has potentially graver significance, but the hypopyon is still generally aseptic.

**Laboratory Procedures**

If corneal infection is suspected, supportive laboratory tests are indicated. The preferred method for obtaining specimens in such instances is to collect tissue directly from the corneal surface with a Kimura platinum spatula (Fig. 60-6). If this instrument is unavailable, a dulled scalpel blade or the blunt end of a scalpel handle may be used. Ideally, corneal specimens are collected before the instillation of topical anesthetics that may inhibit microbial growth. Unless there is a descemetocele or the eye is perforated, aggressive scraping can be performed with little chance of damaging the globe. It is imperative to collect samples both from the center of the lesion and its periphery, since fungi and bacteria, respectively, are most likely to be found at these sites. Particularly in cases of fungal keratitis, scraping from the deeper corneal tissues must be aggressive to obtain diagnostic samples. Material obtained from the first sampling should be inoculated directly onto blood and Sabouraud agar plates. If culture media are unavailable, a commercial Culturette (Becton Dickinson and Co, Cockeysville, Md) offers a more practical, although less desirable, alternative. Subsequent samples are smeared onto glass slides for cytologic evaluation (Figs. 60-7 and 60-8). Separate specimens should be stained with the Gram and the modified Wright-Giemsa (Leukostat; Fisher Diagnostics, Norcross, Ga) techniques. Identification of fungal hyphae is facilitated by using specific stains such as the Gomori methenamine silver, periodic acid–Schiff, and new methylene blues. When fungal infection is strongly suspected but corneal cytology and culture fail to identify organisms, corneal biopsy by lamellar keratectomy is recommended.

**PRINCIPLES OF CORNEAL AND SCLERAL SURGERY**

**Patient Preparation**

Horses with corneas that are perforated or have deep stromal ulcers require special care during preparation for surgery. Anesthetic induction must be performed carefully, preferably with the eye to be operated on protected from injury by padded headgear. Cleansing of the eye must likewise be gentle to avoid perforating deep corneal ulcers and to prevent the dislodging of fibrin plugs that may be sealing an already perforated cornea. Care must be taken to avoid putting pressure on the globe when swabbing the adnexa and conjunctival sac with surgical scrub solutions (see Chapter 55).
Because the large extraocular muscle mass of horses exerts considerable tension on the globe, intraoperative corneal perforation invariably results in anterior displacement of vitreous humor and anterior chamber collapse. Excessive intraocular tension can be prevented either by administering an orbital injection of anesthetic or by augmenting the intraocular tension can be prevented either by administering an orbital injection of anesthetic or by augmenting the therapeutic regimen with a neuromuscular blocking agent31 and deep one third of the cornea. The needle is inserted into the area intended to receive the suture with corneal forceps (Fig. 60-9). The upper teeth of the forceps are imbedded through the epithelium, and the ventral teeth enter the cross-section of corneal stroma at the junction of the middle and deep one third of the cornea. The needle is inserted into the distal cornea at a distance of 1 to 2 mm from the cut suture and, more important, the needle must be sufficiently designed corneal forceps. Many different styles are available, but they all have a 1-to-2 interdigitating tooth design of sufficiently small size to minimize corneal damage. Tooth sizes used for corneal work range from 0.12 to 1.5 mm, with the 0.12- and 0.3-mm teeth being most appropriate for the equine cornea. The Colibri and Castroviejo-Colibri forceps are popular choices that are available with 0.12-mm teeth.

The second most important choice of instrument for corneal surgery is that of the needle holder. Because it is impossible to place micropoint needles accurately with a conventional needle holder, a microsurgical needle holder is essential. As its rounded handle facilitates digital manipulation, the Troutman-Barraquer needle holder with non-locking handle is a good choice. Other less critical but necessary instruments are multipurpose forceps and scissors. For manipulation of the sclera, a forceps with larger teeth is sometimes desired, and for this purpose the Bishop-Harmon forceps is ideal. Corneal section scissors are occasionally necessary for corneal debridement and graft preparation. Other cutting needs in corneal surgery are adequately met with tenotomy scissors (Stevens or Westcott). At least one suture-tying forceps is necessary, and the Harm Harmon forceps is ideal. Conical section scissors are popular choices that are available with 0.12-mm teeth.

Suturing Techniques and Suture Patterns

Because wound dehiscence and leakage of aqueous humor have potentially devastating consequences, correct technique is imperative when suturing corneal and scleral tissues. Corneal sutures are placed by grasping the tissue adjacent to the area intended to receive the suture with corneal forceps (Fig. 60-9). The upper teeth of the forceps are imbedded through the epithelium, and the ventral teeth enter the cross-section of corneal stroma at the junction of the middle and deep one third of the cornea. The needle is inserted into the distal cornea at a distance of 1 to 2 mm from the cut.
edge, depending on the type and intention of the suture pattern being used, in a perpendicular direction. This is important because vector forces limit accurate and controlled needle movement to planes that are perpendicular or parallel with the collagen lamellae. After reaching the desired stromal depth, which ideally is close to but not through Descemet’s membrane, the needle is redirected parallel with the collagen lamellae to exit the deep corneal stroma. Placement of the proximal suture is generally easier because less resistance is offered by the exposed stromal cross-section than by the corneal surface. The tissue on the near side of the wound may be immobilized with the same forceps technique used to make the first bite or by resting the closed forceps against the cornea adjacent to the intended site of needle exit.

Tying forceps, rather than needle holders, are used to tie corneal sutures to prevent suture damage and loss of tensile strength. The Castroviejo corneal forceps are designed with tying platforms for this purpose. In general, a double or triple suture loop is used in the first throw, with two single-loop throws completing the knot. In continuous suture patterns, a fourth throw is indicated to increase knot security. Suture tags are cut to a length of approximately 0.5 mm. For polyglactin 910 (Vicryl, Ethicon, Johnson & Johnson, Somerville, NJ), suture texture limits the tension that can be placed on the knot. For nylon suture, however, it is possible to overtighten knots, thus decreasing suture strength. The proper knot tension is achieved by tightening the second throw to the point of the maximal tension that does not cause the linear arrangement of the first double throw to deviate.

The choice of suture pattern used to close corneal and scleral wounds is dictated primarily by the size of the defect and the health of the surrounding tissue (Fig. 60-10). In simplest terms, acute lacerations with relatively healthy surrounding cornea are usually best closed with a continuous pattern, whereas for large corneal defects in which tension is anticipated or when the ability of the cornea to hold sutures is in question, simple-interrupted patterns, mattress patterns, or both, are necessary. The prime advantage of a continuous suture pattern is that equal tension is applied to all areas of the suture line. Interrupted sutures, in contrast, concentrate the tension in a plane directly between the needle tracks, thus creating uneven tension along the suture line. A continuous pattern, therefore, more effectively seals a corneal incision or wound. The interrupted pattern offers the clear advantage of not relying on only a single knot to provide security. Mattress sutures are usually reserved for occasions when excessive tension on the wound is anticipated. The most common example is the deep stromal ulcer, the closure of which is accomplished with alternating horizontal mattress and simple-interrupted sutures. The choice of suture pattern is also influenced by the suture material being used. Nylon, by virtue of its elastic properties, is less prone to breaking in the event of trauma and is, therefore, better suited for continuous use than polyglactin 910 or silk.

**Keratectomy**

Lamellar keratectomy is commonly carried out in horses for the removal of dermoids and limbal squamous cell neoplasms, to obtain diagnostic corneal biopsies, and in the formation of autogenous corneal grafts. Regardless of the indication, keratectomy is initiated with a corneal incision. The depth and shape of the incision are dictated by the shape of the tissue to be excised. For removal of surface lesions and biopsies, a depth of one third of the corneal thickness is adequate. When fashioning lamellar grafts, inci-
sion depth ranges from one third to two thirds of the corneal thickness. Although most experienced surgeons judge incisional depth by tactile impression, corneal trephines and blades are available with adjustable depth gauges. The shape of a corneal incision to remove limbal lesions is generally triangular, with the apex in the central cornea. Lamellar keratectomy for graft retrieval is performed in either a rectangular or circular configuration.

Despite the thinness of the cornea, the lamellar arrangement of the collagen lamellae makes accurate separation a relatively simple task. After the proper depth has been achieved, collagen lamellae are separated by moving a flat instrument, held parallel with the lamellar plane, in a back-and-forth motion. If the instrument is kept parallel with the cornea, the interlamellar position is maintained and depth is not changed. Corneal disectors (Martinez, Troutman) designed specifically for this purpose have a flat head, a semi-sharp tip, and a curvature that matches that of the cornea. A commercial blade that is sharpened on both sides and at the tip (Beaver 6900 Mini-Blade; R. Beaver, Inc, Waltham, Mass) can be used, but this is not ideal.

**Lamellar and Penetrating Keratoplasty**

Although the term keratoplasty refers to any procedure designed to reshape the cornea, only lamellar and penetrating keratoplasties are routinely performed on horses, most often to treat large corneal defects. The autogenous lamellar keratoplasty is performed by excising a section of the corneal stroma and to prevent incarceration of uvea and-forth motion. If the instrument is kept parallel with the cornea, the interlamellar position is maintained and depth is not changed. Corneal disectors (Martinez, Troutman) designed specifically for this purpose have a flat head, a semi-sharp tip, and a curvature that matches that of the cornea. A commercial blade that is sharpened on both sides and at the tip (Beaver 6900 Mini-Blade; R. Beaver, Inc, Waltham, Mass) can be used, but this is not ideal.

**SURGICALLY MANAGED DISORDERS**

**Dermoids**

Congenital dermoids are effectively removed by one-third-depth lamellar keratectomy. The corneal incisions are usually made in clear cornea, extending from the limbus adjacent to the lesion to an apex point in clear cornea. Lamellar dissection is started at the apex of the keratectomy site, ending at the limbus. For dermoids that involve the sclera, the keratectomy is continued across the limbus into superficial sclera and Tenon’s capsule. Once beyond the margins of the dermoid, corneal section scissors are used to transect the base of the tissue to be removed.

**Lacerations**

Lacerations of the equine cornea and sclera are among the most common corneal problems requiring surgical management. For penetrating lacerations with little adjacent corneal damage, correction is easily effected by closure in a simple-continuous pattern. Because the cornea is not perforated, 8-0 suture material is adequate. Perforating lacerations with little secondary corneal or uveal damage may be closed in an identical fashion, particularly if the wound is small.

Perforating corneal lacerations with uveal prolapse are managed by first gently removing adhered fibrin from the incarcerated uveal tissue with thumb forceps. Care must be taken to avoid traumatizing the iris and inducing hemorrhage. The integrity of the corneal seal, however, should not be broken until the wound margins are fully visualized, the problem is assessed, and a decision is made as to the appropriate surgical procedure. The decision of whether to amputate prolapsed uveal tissue is then made. The increased potential for uveal hemorrhage, hyphema, and postoperative uveitis mandates that iridectomy be performed only if the prolapsed tissue is excessive or necrotic. Uveal tissue that has been prolapsed for as long as 3 to 4 days, if protected by a fibrin cover, can be safely returned to the anterior chamber. If uveal amputation is necessary, cautery is the preferred method because hemorrhage is minimized. If scissors must be used, and hemorrhage does occur, gentle intraocular irrigation with a dilute (1:10,000) epinephrine borate solution is beneficial.

Before the placement of corneal sutures, it is critical that uveal adhesions be broken sufficiently to allow visualization of the corneal stroma and to prevent incarceration of uvea in the sutured wound. An iris spatula is useful for this procedure: it is gently passed between the iris and the corneal margins. It is imperative that uveal manipulation be minimized to prevent significant postoperative uveitis. If the prolapse is small, it is gently tucked into the anterior chamber prior to wound closure. Ideally, an effort should be made to minimize anterior synechiae. All too often, however, iris swelling precludes wound closure without contact between iris and endothelium. It is important to appreciate that focal anterior synechiae are far less significant complications than the uveitis induced by aggressive uveal manipulation. The corneal wound is closed with 7-0 polyglactin 910 in a simple-interrupted or simple-continuous suture pattern, depending on the size of the wound (Fig. 60-11). If uveal tissue attempts to escape from the wound during closure, it is necessary to pre-place interrupted sutures while an assistant depresses the uveal tissue with an iris spatula.

When the corneal wound is securely closed, the anterior chamber depth is assessed. This is important because irido-corneal adhesions, if extensive, may result in postoperative angle closure, leading potentially to glaucoma development.

**Figure 60-11.** Appearance of a corneal laceration immediately after surgical correction.
In many cases, particularly if the wound is small and the injury acute, the anterior chamber will have filled with aqueous humor by the time surgery is complete. If it has not, it should be filled by injection of irrigation solution (saline, balanced salt solution, or lactated Ringer’s solution) or with the more viscous hyaluronic acid (Hyalartin V, Pfizer Animal Health, New York, NY). If the anterior chamber is extremely shallow, a small air bubble is injected to keep the iris from contacting the cornea; air is superior to fluid under these circumstances because it will not be forced through the iridocorneal angle by increased intraocular pressure. The chamber is filled, by injecting either through the wound with a 30-gauge injection cannula or through the limbus with a 27-gauge needle. Hyaluronic acid can be injected with a 20-gauge needle at the limbus. The latter technique will maintain the anterior chamber depth for a longer time.

Large corneal lacerations are handled in an identical fashion, except that ureal presentation is more difficult to manage, and corneal closure may require the use of mattress sutures to improve wound security. If the cornea is weakened by the effects of inflammation, the sutured defect should be covered with a conjunctival graft or filled with a corneal graft. Wounds involving the sclera are handled similarly. It is important to distinguish, however, between corneal and scleral lacerations and globe ruptures. The fibrous tunic of horses is prone to rupture on impact with blunt objects. The injury may appear grossly similar to a sharp laceration, except that these “blow-out” injuries tend to be larger, often extending from limbus to limbus, and are invariably associated with considerable hyphema. In such cases, enucleation or evisceration and intraocular prosthesis implantation are more appropriate choices of therapy.

**Corneal Suturing**

Corneal sutures may be used to close deep ulcers and descemetocyes that are less than 2 mm in diameter. The choice of suture pattern depends on the degree of anticipated tension and suture-holding ability of the cornea; however, in general only interrupted sutures are used for this purpose. The closure is initiated by pre-placing two horizontal mattress sutures across the corneal defect. Because considerable suture tension is anticipated, 6-0 suture material may be necessary. The normal intraocular pressure exerts considerable tension on the cornea, which makes it difficult to appose the ulcer margins without creating excessive suture tension. In addition to suture breakage, the pressure may cause the suture to cut through the tissue. This problem is handled in one of two ways. First, the mattress sutures may be tied in a gradually alternating fashion over a several-minute period. This allows aqueous humor to be forced through the iridocorneal angle and the anterior chamber to decrease in size. Alternatively, a 25-gauge needle is inserted into the anterior chamber, and 0.25 mL of aqueous humor is withdrawn to relieve the tension. The mattress sutures are subsequently alternated with simple-interrupted sutures. The anterior chamber is re-inflated, if necessary, as described for corneal lacerations.

**Corneal Grafting**

Perhaps the most difficult corneal injury to manage is the deep corneal ulcer that exceeds 5 mm in diameter. Because the defect is too large for direct suturing, a grafting technique is necessary. If corneal transparency is not a surgical objective, conjunctival grafts may be used; however, corneal grafts are preferable because they provide greater structural support.

**SLIDING LAMELLAR CORNEAL GRAFTS**

A sliding lamellar graft (Figs. 60-12 and 60-13) is started by preparing the recipient bed. Because most ulcers are circular, this usually involves little more than débriding loose and necrotic corneal tissue from the ulcer margins with a no. 64 Beaver blade. If the ulcer has irregular margins, corneal scissors should be used to trim the edges to make them as smooth as possible. The decision of whether to harvest the graft from tissue directly adjacent to the defect, leaving bulbar conjunctiva attached, or from a distant corneal site, is left to the surgeon. The primary advantage of harvesting the graft from tissue adjacent to the ulcer is that the graft depth can be accurately judged against the width of the ulcer. In this case, the graft is prepared by extending parallel corneal incisions from the ulcer’s widest margin to the nearest limbus. The graft thickness should be one half to two thirds the thickness of the cornea. Using scissors, the incisions are extended into the conjunctiva along a line slightly diverging from the corneal incisions. The graft is then lifted free of the underlying cornea by lamellar dissection, as described for keratectomy. When the limbus is reached, the dissection is beveled in a superficial direction to connect with the subconjunctival space, thus creating a corneal–conjunctival transposition flap. Dissection may be directed deeper into the sclera to create a corneal and scleral transposition flap; however, postoperative corneal opacification tends to be greater. After the conjunctiva is undermined by blunt dis-
section, the graft’s leading margins are sculpted to conform to the contour of the recipient bed. The graft is subsequently sutured into place with 7-0 or 8-0 polyglactin 910 sutures in a simple-interrupted pattern.

The sliding lamellar graft may also be used to reconstruct perforated ulcers. A uveal prolapse is managed as a laceration (described earlier). Creating an effective corneal seal, however, is difficult in these cases, because leaking aqueous humor from the perforation site readily undermines the graft and gains access into the subconjunctival space. This is prevented by suturing the conjunctiva, at the graft margin, to the underlying cornea. Sutures should not be so numerous, however, to obstruct the blood supply to the graft.

FREE LAMELLAR CORNEAL GRAFTS

When performing a free lamellar graft, tissue should be harvested from the inferior medial cornea so that the donor bed is protected postoperatively by the nictitating membrane. The donor button may either be excised with a corneal trephine or by scalpel incision. If a trephine is used, the donor button should have a diameter that is 1 mm larger than the area to be grafted. When using a blade to collect the graft, a rectangular button is excised and then trimmed to fit the defect.

CORNEAL TRANSPLANTATION

Corneal transplantation is a viable and successful surgical technique in the horse. Full-thickness penetrating keratoplasty (PK) may be performed for melting ulcers, iris prolapse or descemetoceles, and full-thickness stromal abscesses.44 Deep lamellar endothelial keratoplasty (DLEK) and posterior lamellar keratoplasty (PLK) are split-thickness penetrating keratoplasties used for deep stromal abscesses with clear overlying anterior stroma. Frozen donor grafts can be used successfully for transplants in the horse eye. Corneal transplants in horses are associated with high success rates, good visual outcomes (greater than 80%), and shorter treatment times than medical treatment alone for these eye problems, but the corneal transplants in horses do vascularize, have some degree of opacity, and thus exhibit some degree of graft rejection.

PENETRATING KERATOPLASTY

Penetrating keratoplasty involves full-thickness removal and replacement of a portion of the cornea. Corneal sutures are necessarily utilized to heal a vertical stromal incision with an associated disruption of the corneal surface and topography. Topical serum and cyclosporine A are added postoperatively. The surgical approach for PK in horses is as follows.

Donor corneal material is harvested preferentially from fresh or frozen equine cadaver eyes (i.e., within 24 hours of death). The size of the lesion is determined with calipers. A full-thickness button of cornea that is 1 mm larger than the recipient bed is trephined from the endothelial to the epithelial side of the donor cornea. The ideal graft size in horses is 6 to 8 mm in diameter, but larger grafts are
possible. The donor button is grasped with fine-toothed forceps (while paying particular attention to the orientation of the epithelium and endothelium), placed on a gauze sponge, and kept moistened with lactated Ringer’s solution. The epithelium is not removed from the corneal donor button.

The recipient globe is stabilized with scleral fixation sutures of 5-0 nylon (Ethicon, Johnson & Johnson). A corneal trephine of appropriate size (i.e., 6 to 8 mm or greater) is centered over the diseased area and then rotated with minimal downward pressure to obtain a clear-cut, round incision with vertical sides. The incision with the trephine approaches to just near Descemet’s membrane.

The remaining intact deep stromal tissue is vertically incised with a no. 65 Beaver blade to enter the anterior chamber, being careful to avoid the iris, corpora nigra, and lens. The button of diseased host tissue is then removed with corneal section scissors. The keratectomy button is processed for culture and sensitivity, cytology, and histopathology.

Bulging of the iris and the corpora nigra into the incision site may occur. Adhesions or synechia between the abscess and iris may be present. The anterior chamber is re-formed by injecting hyaluronic acid solution into the anterior chamber. The viscoelastic solution also moves the iris posteriorly and breaks down any adhesions between the abscess and the iris. Direct contact with the lens capsule is also avoided by re-forming the anterior chamber with the viscoelastic solution.

The donor cornea is removed from the moistened gauze swab and placed in the recipient bed, and four cardinal sutures of 8-0 polyglactin 910 or 9-0 nylon are placed at the 12-, 6-, 9-, and 3-o’clock positions. Simple-interrupted sutures are placed to fill in the remaining sectors in each quadrant, or alternatively, a simple-continuous suture pattern can be placed to hold the graft. Once the donor cornea is sutured into place (Fig. 60-14), viscoelastic solution may again be injected via a limbal incision to re-form the anterior chamber.

SPLIT-THICKNESS PENETRATING KERATOPLASTY
In some deep stromal abscesses, the superficial cornea is vascularized but otherwise normal. For horses with deep stromal abscesses and anterior chamber fungal invasions that persist, or even progress, with severe pain and vision-threatening uveitis in the face of aggressive medical therapy, surgical removal of the posterior stroma and endothelium containing the abscess by corneal transplantation is warranted.

The inherent philosophy of split-thickness or lamellar surgery is to replace only the diseased portion of the cornea, leaving the normal tissue intact—in other words, to do the least amount of resection for the greatest amount of benefit.44,45 Both the PLK and DLEK surgical methods are forms of split-thickness PK, because they avoid removal of superficial normal tissue but do surgically enter the anterior chamber.44,45 These surgical methods are important for resolving deep stromal abscesses with anterior chamber invasion in horses.

POSTERIOR LAMELLAR KERATOPLASTY
Posterior lamellar keratoplasty is recommended for deep stromal abscesses in the central cornea that are 8 mm or less and that have a clear overlying anterior stroma. Topical serum and cyclosporine A are added postoperatively. The surgical approach for PLK in horses is as follows.

A rectangular, anterior lamellar corneal flap, hinged on one side, is constructed by hand dissection to two thirds of the stromal thickness over the stromal abscess. A Martinez corneal dissector is used to undermine and elevate the superficial corneal layers to expose the abscess. The flap is gently raised, and a trephine, a no. 65 Beaver blade, and corneal scissors are used to remove the posterior stromal abscess, Descemet’s membrane, and endothelium. The anterior chamber is re-formed with viscoelastic solution. A circular graft (of posterior stroma, Descemet’s membrane, and endothelium) 1 mm larger than the defect is cut from donor tissue using a trephine. The graft is placed in the corneal defect and sutured every 2 mm using 8-0 absorbable suture material in a simple-interrupted pattern (Fig. 60-15). The three-sided superficial flap is then sutured in place using 8-0 absorbable suture material. A partial temporary

Figure 60-14. A penetrating keratectomy (PK) graft sutured into place.

Figure 60-15. Three-sided posterior lamellar keratoplasty (PLK) immediately after surgery.
tarsorrhaphy is always placed to protect the graft during recovery.

The PLK is associated with a shorter surgery and treatment time than the PK. Complications of PLK include superficial suture abscesses, suture incision leaks, flap ulcers, and flap edema. The donor graft remains transparent for up to 7 days and then opacifies. Partial graft rejection and scar formation have been unavoidable for both the PK and PLK procedures. PLK and PK result in similar scars, which are typically vascularized and eventually opaque. The visual outcome is greater than 90% for the eyes that have the PLK procedure.

DEEP LAMELLAR ENDOThelial KERATOPLASTY
The deep lamellar endothelial keratoplasty is recommended for deep stromal abscesses in the peripheral cornea that are 6 mm or less and have a clear overlying anterior stroma. It avoids the superficial incisions and suturing of the central cornea. The DLEK transfers healthy endothelium while preserving the corneal surface integrity. A fully intact epithelium with no corneal sutures is present postoperatively. The surgical approach for DLEK in horses is as follows.

A two-thirds depth, limbal incision up to 23 mm in length is made with a no. 64 Beaver blade. A stromal pocket is formed over the deep stromal abscesses with a Martinez corneal dissector. Bleeding from the vascularized cornea is controlled with electrocautery. The superficial corneal flap is gently retracted, and the abscess is removed with a trephine, a no. 65 Beaver blade, and corneal scissors. The anterior chamber is re-formed with viscoelastic solution. The anterior two thirds of the donor cornea is removed by hand dissection, and a trephine 1 mm larger in diameter than the recipient site used to obtain the circular donor graft from the remaining split-thickness cornea. The donor graft is inserted into place with Utrata forceps, and the limbal incision is closed (Fig. 60-16). The graft adheres to the recipient stroma by action of the endothelial pump, but it may need to be positioned in place by a needle inserted between the flap sutures, or at the limbus. The graft is supported by the viscoelastic solution in the anterior chamber, which can be safely left in situ. A partial temporary tarsorrhaphy is always placed to protect the surgical site during recovery. Medical therapy postoperatively includes topical atropine, cyclosporine A, autogenous serum, topical antifungals and antibiotics, systemic antibiotics, and nonsteroidal anti-inflammatory drugs.

Neoplasia (Squamous Cell Carcinoma)
The most common tumor requiring corneal surgery is squamous cell carcinoma (Fig. 60-17). Because these tumors generally occur at the limbus, both cornea and sclera are generally involved. Numerous surgical options are available.

Lamellar Keratectomy
Lamellar keratectomy is predictably successful because intraocular tumor extension is inhibited by the dense collagen arrangement of the corneal stroma. One-third-depth keratectomy is therefore usually adequate.

Cryotherapy
Cryosurgery is also effective for destroying limbal tumors. Liquid nitrogen, the preferred cryogen, may be applied either as a fine spray or via a copper contact probe. The objective is to reduce the tissue temperature to ~−20 °C (~−4 °F). Because thermocouples are unsuitable for corneal implantation, the extent of freezing must be judged subjectively. The ice-ball should be allowed to extend 1 to 2 mm beyond the visible margins of the tumor. A double freeze–thaw cycle is recommended. The primary disadvantage of cryosurgery is the potential for nonselective destruction of normal tissue; corneal stromal and endothelial damage are potential complications.

Laser Ablation
The effective use of carbon dioxide laser ablation in treating limbal squamous cell carcinomas has been described. The carbon dioxide laser emits a beam in the infrared spectrum (10,600 nm) that exerts a thermal tissue effect whose physical characteristics are determined by the power density of the beam. If the beam is focused, the tissue is incised,
whereas a defocused beam of lower energy density diffusely vaporizes the exposed tissue. The latter application is ideally suited for excision of superficial neoplasms. Treatment may be performed with local anesthesia; however, general anesthesia is recommended. The laser is operated in the continuous mode with power settings of 3 to 8 W. Either continuous energy release or timed bursts may be applied, depending on the surgeon’s preference. The tumor tissue is ablated until charred superficial stroma remains, and healing occurs in 30 days (Fig. 60-18). For very large tumors, the mass may be debulked by conventional excision prior to laser applications. Advantages of laser vaporization of neoplasms include (1) simultaneous coagulation of small vessels, (2) coagulation of nerve endings, resulting in minimal postoperative discomfort, (3) predictable excision depth without damage to adjacent normal tissue, and (4) the stimulation of a beneficial immune response.

**Other Techniques**

Small (less than 5 cm) limbal squamous cell carcinomas also may be treated successfully with radiofrequency hyperthermia. In this procedure, contact probes are placed on either side of the tumor, and tissue is destroyed by raising its temperature to 50°C (122°F). Limbal squamous cell carcinomas are amenable to brachytherapy with strontium-90 probes; a radiation dose of 25,000 rad has been recommended. However, Sr therapy is effective only for tumors less than 2 mm in thickness. Immunotherapy with bacillus cell wall extract, used successfully to treat squamous cell neoplasms at other sites, is not applicable for limbal tumors.

**AFTERCARE**

**Medical Therapy**

For surgical procedures involving the cornea and sclera specifically, topical antibiotics are always indicated. The choice of drug, vehicle, and administration route, however, varies with the surgical procedure and needs of the patient.

For elective procedures performed on intact globes (e.g., keratotomy, cryosurgery, and CO2 laser ablation), broad-spectrum antibiotics are applied four times a day. Because of its wide antimicrobial spectrum and predictable efficacy against gram-positive organisms, triple antibiotic (neomycin, bacitracin, and polymyxin) is preferred. Solutions are difficult to administer to horses without the benefit of some type of lavage catheter, so ointment is preferred for topical therapy of low frequency. Acute lacrations are also adequately treated with topical therapy with triple antibiotic ointment four times a day. For subacute lacrations and ulcers requiring surgery, however, topical therapy may be indicated from every 4 hours to every 1 hour, depending on the severity of corneal infection. In these cases, an antibiotic solution is applied through a subpalpebral lavage catheter.

**Adjunctive Therapy**

**Contact Lenses**

Hydrophilic corneal contact lenses (Equus, The Cutting Edge, Santa Clara, Calif) in diameter sizes of 26 to 34 mm (base curve, 15 to 18 mm) are available for horses at an approximate cost of $60. Contact lenses can be used to protect ulcerated or lacerated corneas and may be used postoperatively to protect sutured corneas.
contraindicated, however, for use in infected ulcers and are poorly effective for managing ulcers with impending perforation. A major limitation of contact lenses in animals is the tendency for them to become dislodged by movement of the nictitating membrane.

COMPLICATIONS

The most important complications of corneal and scleral surgery are related to concurrent intraocular tissue damage or to dehiscence of sutured wounds. As mentioned previously, phthisis bulbi is a common sequela to traumatic globe injuries and particularly to traumatic globe rupture. If the globe is going to undergo significant phthisis, it will generally be apparent within 30 days of the injury. Enucleation should not be elected hastily, as horses possess a unique ability to undergo partial phthisis and still retain vision. Wound dehiscence most commonly occurs after closure of corneal and scleral perforations, particularly if the wound was infected at the time of the surgery. If, in the surgeon's opinion, vision is potentially salvageable, the wound should be closed again and supported with a conjunctival flap, or a corneal graft should be applied. If wound dehiscence is chronic or associated with large uveal perforation, enucleation is often the most practical alternative. Intraocular infection appears to be the least common complication of corneal or scleral surgery. This is because of the efficacy of prophylactically applied antibiotics, as well as the tendency of fibrin and uveal tissue to seal corneal and scleral defects effectively at the time of perforation. When intraocular infection does occur, however, it almost always necessitates enucleation, because of the difficulty in achieving effective intraocular antibiotic concentrations.

REFERENCES

The iris is composed of an anterior border layer with fibroblasts and melanocytes (in pigmented irides), the stroma (making up the bulk of the iris), and a double layer of posterior pigmented epithelium. The stroma contains the smooth muscle of the pupillary sphincter as well as melanocytes (in pigmented irides), collagen fibrils, fibroblasts, nerves, and blood vessels. At the level of the last ciliary process runs the incomplete major arterial circle of the iris (incomplete at 12 and 6 o’clock), which is a continuation of the long posterior ciliary arteries. Radial vessels from this incomplete circle pass to the pupil and also to the ciliary body. There is another incomplete arterial circle at the level of the sphincter muscle, with small arterioles continuing into the corpora nigra. The capillary endothelium is not fenestrated and probably represents the anatomic blood–aqueous barrier in the iris. A double layer of pigmented epithelium lines the posterior surface of the iris. The anterior layer of cells forms the iris dilator muscle, which is poorly developed in the horizontal axis. Proliferations of the two layers of epithelium form the corpora nigra.

CHAPTER 61

Intraocular Surgery
Joan Dziezyc

ANATOMY

Iris
The iris comprises the most anterior part of the uveal (vascular) tract. The colors of the equine iris vary from blue to dark brown. The pupil is horizontally oriented with large corpora nigra (granula iridica) superiorly and much smaller corpora nigra inferiorly (Fig. 61-1).

The iris is composed of an anterior border layer with fibroblasts and melanocytes (in pigmented irides), the stroma (making up the bulk of the iris), and a double layer of posterior pigmented epithelium. The stroma contains the smooth muscle of the pupillary sphincter as well as melanocytes (in pigmented irides), collagen fibrils, fibroblasts, nerves, and blood vessels. At the level of the last ciliary process runs the incomplete major arterial circle of the iris (incomplete at 12 and 6 o’clock), which is a continuation of the long posterior ciliary arteries. Radial vessels from this incomplete circle pass to the pupil and also to the ciliary body. There is another incomplete arterial circle at the level of the sphincter muscle, with small arterioles continuing into the corpora nigra. The capillary endothelium is not fenestrated and probably represents the anatomic blood–aqueous barrier in the iris. A double layer of pigmented epithelium lines the posterior surface of the iris. The anterior layer of cells forms the iris dilator muscle, which is poorly developed in the horizontal axis. Proliferations of the two layers of epithelium form the corpora nigra.

which opens the drainage angle and alters the shape of the
lens, is poorly developed in the horse.

**Ciliary Body**
The ciliary body is the midportion of the uveal tract found
between the iris and the choroid plexus. It is made up of the
ciliary processes anteriorly (pars plicata) and a flattened area
posteriorly (pars plana). Zonular fibers insert on the pars
plicata and pass to the pars plana.
The ciliary body is lined with a double layer of epithelium: the inner layer is nonpigmented, and the outer layer
pigmented. Junctions between the apical ends of the non-
pigmented epithelium probably represent the anatomic
blood–aqueous barrier in the ciliary body.1
The ciliary body stroma is made up of connective tissue,
numerous blood vessels, nerves, and melanocytes. Capillaries
contain fenestrated endothelium. The radial ciliary muscle,
which opens the drainage angle and alters the shape of the
lens, is poorly developed in the horse.

**Lens**
The lens is positioned behind the iris and held in place by
numerous zonules, which run from the ciliary body and
insert at the lens circumference. The lens consists of the lens
capsule, anterior and equatorial epithelium, and lens fibers.
The horse's lens measures about 20 mm in diameter and
13 mm in depth anteroposteriory.
The lens in young animals is very elastic and changes
shape with differing zonular tension. This in turn is controlled
by the action of the ciliary muscles. The focusing ability of horses is much less than that of humans.
The lens capsule completely surrounds the lens and is the
basement membrane of the lens epithelium. Only the anterior surface of the capsule is lined by epithelium in the
mature lens. Lens epithelial cells at the lens equator continue to divide during life, creating new cells that elongate
to form lens fibers. The most recently formed lens fibers
are found under the lens capsule (in the lens cortex), and
the oldest fibers are found in the center of the lens (in the
lens nucleus). Lens sutures lines are most easily seen in young animals and represent the junctions between the ends
of the lens fibers that have become apposed as the fibers grow toward opposite sides of the lens.

The posterior segment of the eye is filled with vitreous.
The vitreous is mostly made up of water with a collagen–
hyaluronic acid network and a few cells called hyalocytes.
The vitreous is attached to the eye at the optic disc, by the vitreous base at the ora ciliaris retinae, and by the hyaloideocapsular ligament at the posterior lens capsule.
The posterior area of the globe is made up of retina, choroid, and sclera. The sclera is the outer fibrous layer of the
globe, continuous with the cornea at the limbus. The choroid is the posterior uveal (vascular) layer, continuous with the ciliary body anteriorly. The choroid consists mainly of
blood vessels, which provide nutrition to the retina and optic nerve. Arteries are branches of the short posterior
ciliary arteries that enter the globe near the optic nerve. Capillaries are fenestrated. The choroid also contains melanocytes and fibroblasts, collagen and elastic fibers, and the
tapetum. In horses, the tapetum is mainly acellular, composed of lamellae of collagen fibrils. The tapetum is found
in the superior half of the fundus.
The retina represents the inner layer of the posterior globe and is divided into two layers: (1) the neurosensory, inner
retina, which contains photoreceptors and neurons, including
ganglion cells whose axons form the optic nerve; and (2) the retinal pigment epithelium, the outer layer, which
is important in the maintenance of the photoreceptors. Retinal detachments occur between the neurosensory layers
and the retinal pigment epithelium. The intraocular optic
nerve in horses is nonmyelinated and is seen as a large
oval in the nontapetal region, just below the tapetal–
nontapetal junction. The retina of a horse is pauprangiopic, with retinal vessels extending only a short distance from the
optic disc.

**IMMUNOLOGY**
The major problem associated with intraocular surgery in horses is postoperative inflammation (uveitis). The act of
incising the eye, or performing a paracentesis, causes a
cascade of events that, if not modified, may end in a phthisic
eye. Inflammatory mediators that are released include prostaglandins, leukotrienes, and prostacyclin.2 These mediators cause miosis, dilation and increased permeability of
uveal blood vessels, and production of a plasmoid aqueous
(a breakdown of the blood–aqueous barrier). Opening the
lens capsule during cataract surgery causes inflammation
by exposing the eye to large amounts of lens proteins. Normally, lens protein is semiserquestered from the body by
the lens capsule. Low levels of circulating lens antigens nor-
manly maintain a tolerance to these proteins.3 When large
amounts of lens protein are liberated or normal tolerance
is altered, autologous lens protein can initiate immune-
mediated uveitis.6

Unless the inflammatory response is altered by drugs, sequelae can be expected, including posterior synechiae, cataract formation, corneal edema, chorioretinitis, retinal
detachment, and phthisis bulbi.

Additional information on other causes of uveitis and its
control can be found in Chapters 62 and 64.
**DIAGNOSTIC PROCEDURE: PARACENTESIS**

Paracentesis pertains to the removal of either aqueous from the anterior chamber (anterior chamber paracentesis) or removal of liquefied vitreous from the posterior segment of the eye (vitreal paracentesis). Paracentesis is a procedure used in the diagnosis of uveitis when conventional diagnostic aids have failed and therapy is unrewarding. It is valuable when endophthalmitis is suspected. Paracentesis is not without risks; the potential for damage to the eye exists. Also, paracentesis is often unrewarding in terms of making a diagnosis. However, if a diagnosis cannot be made any other way and the eye is not improving with treatment, paracentesis should be performed. A paracentesis should be followed up with an injection of an antibiotic, an antifungal agent, and a tissue plasminogen activator (to dissolve fibrin deposits) if any of these treatments are indicated.

Anterior chamber paracentesis can be performed under general anesthesia, or with eyelid blocks in a heavily sedated horse. General anesthesia carries less risk to the eye but more risk to the horse. A lid speculum is used to open the eyelids. Topical anesthetic is applied to the cornea and conjunctiva. Subconjunctival lidocaine should be injected over the paracentesis site in a sedated horse. The conjunctiva is grasped near the limbus with small-toothed forceps, and a 25-gauge (or smaller) needle attached to a 1-mL syringe is inserted under the conjunctiva, through the limbus, and into the anterior chamber (Fig. 61-2). The needle should be directed parallel to the plane of the iris. No more than 0.5 mL should be removed. For a vitreal aspirate, a 22- to 23-gauge needle is used. The author has performed these aspirates only under general anesthesia. The needle is inserted 10 mm behind the limbus at the 12-o’clock position, through conjunctiva, sclera, and the pars plana of the ciliary body, and directed toward the posterior pole of the eye to avoid traumatizing the lens. Because the needle often cannot be observed, vitreous paracentesis carries a greater risk of injury to the eye.

Aspirates should be cultured for aerobic as well as anaerobic bacteria, and fungal cultures should be performed if appropriate. Cytology of the aspirate may be most informative. In cases of suspected endophthalmitis, antibiotics should be injected into the vitreous. Antibiotics may stabilize the eye, but enucleation may still be necessary because of intractable uveitis.

**SURGICALLY MANAGED DISORDERS**

For intraocular surgery to be successful in any species, several requirements have to be satisfied. First, the surgeon must be trained in microsurgery and must perform enough intraocular procedures to stay competent. Second, a means of magnification, usually an operating microscope, and microsurgical instruments must be available. Third, close work with anesthesiologists is necessary because a motionless eye is very important in intraocular procedures, which may require concomitant use of inhalation anesthesia, muscle relaxants, and narcotics. Finally, patient selection and follow-up therapy are especially important. Horses' eyes are more reactive than eyes of other domestic species, and close follow-up with changes in therapy, when appropriate, is extremely important. For example, equine cataract patients often remain hospitalized for 3 to 4 weeks to ensure adequate postoperative therapy.

**Iris and Ciliary Body**

Surgery of the equine iris and ciliary body is performed rarely. Iridectomy has been described for treatment of an iris melanoma.7 The use of lasers allows manipulation of the anterior uvea without entering the eye. Both the Nd:YAG and diode lasers have been used to shrink or destroy anterior uveal tumors in horses. The diode laser also has an endoprobe that can be used in the anterior chamber through a small incision.

**Epithelial Iris Cysts**

Occasionally, horses are presented with visual deficits secondary to iris cysts associated with the corpora nigra. These can be opened in several ways. Under general anesthesia, a 20-gauge needle can be inserted into the anterior chamber through the limbus and used to lacerate the cysts. Alternatively, the use of lasers allows opening of the cysts without entering the eye and therefore carries a better prognosis. Lasers can also be used on a standing, sedated horse, eliminating the need for general anesthesia. Nd:YAG, argon, or diode lasers have been used. One report8 describes treating eight horses with large corpora nigra cysts with the Nd:YAG laser. Clinical signs, including vision problems, resolved after laser therapy.

**Lens**

**Cataract**

Cataracts are optical opacities in the lens. They range in size from minute opacities that can be seen only with magnification, to opacities that involve the entire lens. Vision may (or may not) be impaired, depending on the size and location of the cataract.

Cataracts can be seen in animals of any age and have a number of different causes. In horses, cataracts most commonly develop secondary to periodic ophthalmia (equine...)

---

*Figure 61-2. Paracentesis of the anterior chamber. A 25-gauge needle attached to a 1-mL syringe is inserted into the anterior chamber at the limbus, and fluid is withdrawn.*
Another common cause is trauma, usually either a perforating or a concussive injury. Congenital cataracts are seen less frequently. Most congenital cataracts are assumed to occur spontaneously, although inherited congenital cataracts have been described in the Belgian Draft horses, associated with aniridia; in Morgan horses, where cataracts were nuclear and affected animals had no visual deficits; and in the Rocky Mountain horse with nuclear cataracts associated with multiple anterior segment anomalies. Often, congenital cataracts are associated with varying degrees of microphthalmia.

Patient selection is an important part of cataract removal in horses. The best candidate is a horse with a cataract uncomplicated by any other ocular problems. Uncomplicated cataracts are seen more frequently in young animals with congenital cataracts than acquired cataracts in adult horses. Ocular problems that worsen the prognosis but are not a contraindication for surgery include (1) microphthalmia; (2) evidence of perforating trauma, such as a full-thickness corneal scar, or small synechiae; and (3) evidence of mild uveitis, such as a darkened iris or a pupil that does not dilate as well as the normal eye. Evidence of periodic ophthalmia (equine recurrent uveitis, moon blindness) is a contraindication for cataract surgery in the author’s clinic. Signs of periodic ophthalmia include corneal edema, multiple posterior synechiae, aqueous flare, retinal detachment, chorioretinal scars (especially around the optic disc), and phthisis bulbi.

If the retina cannot be seen through clear areas of the lens (i.e., when the cataract is mature), ultrasonography is used to image the posterior aspect of the eye. Ultrasonography can detect retinal detachments, posterior capsular ruptures, lenticonus, vitreal abnormalities, and optic nerve colobomas.

Preoperative and postoperative treatments include topical mydriatics or cycloplegics, such as atropine; topical anti-inflammatory drugs such as corticosteroids (prednisolone acetate 1.0%, dexamethasone 0.1%); a nonsteroidal anti-inflammatory drug (flurbiprofen); and topical antibiotics. In addition, systemic antibiotics are used perioperatively, and systemic nonsteroidal anti-inflammatory drugs (flunixin meglumine) are used. These drugs are used to dilate the pupil, to decrease the inflammation induced by the surgery, to decrease pain, and to attempt to sterilize the surgical site. Drugs are used for 1 to 2 days before surgery in quiet eyes, and for as long as necessary in eyes with low-grade uveitis. Drugs are used postoperatively for at least 3 weeks and often longer.

PHACOFRACTMENT

Surgery is performed using phacofragmentation (Fig. 61-3). Phacofragmentation refers to the use of ultrasonic waves to break up the lens. The lens particles are subsequently aspirated from the eye. Various techniques for phacofragmentation are used in different clinics. The technique used by the author is described.

The horse is positioned in lateral recumbency. A 19-gauge irrigating cannula is inserted through a clear corneal incision. Lactated Ringer’s solution is continuously infused through this cannula. A limbal-based conjunctival flap is dissected, a partial-thickness limbal incision is created, and the anterior chamber is entered with a stab incision. A cystotome, made by bending the tip of a 23-gauge needle, is inserted through the incision and used to tear and remove the majority of the anterior lens capsule (see Fig. 61-3). A 17-gauge, 4-cm, blunt-tipped needle with a 30-degree bevel attached to the handpiece of a modified lithotriptor (Fibronics Lithotriptor, Fibronics, Chicago, Ill) is inserted into the eye and held by the surgeon’s dominant hand. Aspiration is performed by a phacoemulsifier aspiration unit (Model 8000[IV] Cavitron/Kellman Phaco-Emulsifier Aspirator, Cooper Vision, Irvine, Calif) attached to the handpiece. Ultrasonic waves break up the lens into particles, which are aspirated from the eye. When the entire lens cortex and nucleus are removed, the lithotriptor needle is removed from the eye. The corneal incisions are closed with two or three simple interrupted sutures of 7-0 polyglactin (Vicryl, Ethicon, Somerville, NJ) to provide a watertight seal. The conjunctival incision is closed with a simple-continuous...
pattern using the same suture material. A subpalpebral lavage system (see Chapter 55) is placed.

When a modified lithotriptor is not available, veterinary ophthalmologists using standard human phacofragmenters, whose tips are too short to cross the entire lens capsule of a horse, may have to make more than one corneal incision to remove all the lens material.\textsuperscript{15}

Phacofragmentation works well in horses because only a small incision is used, perfusion is constant, and the eye does not collapse. Additionally, all lens fibers can be removed from the eye, eliminating this potentially antigenic material. The use of muscle relaxants such as pancuronium or atracurium establishes a motionless eye with minimal vitreal and posterior capsular movement. This results in a considerable shortening of the operative time and a decrease in the amount of irrigating solution used.

**PROGNOSIS**
Several recent publications have looked at the success (in horses) of lens removal by phacofragmentation. Fifty-one eyes in 36 horses were operated on at the institution of this author.\textsuperscript{14} Useful vision was restored in 30 horses in the immediate postoperative period. At 1 year or longer, 16 out of 19 horses were visual. Three of these horses were followed for 5 years or longer. Postoperative complications included corneal ulcers, excessive anterior chamber fibrin deposition, diffuse corneal edema, elevated intraocular pressure, and most devastatingly, endophthalmitis in four eyes of three horses. *Streptococcus zooepidemicus* was cultured from three of these eyes. Tissue plasminogen activator (25 µg) was injected into the aqueous of eight eyes and successfully caused dissolution of fibrin in these eyes.

In a report from The Ohio State University, 47 eyes in 39 horses were operated on with phacofragmentation. Similar postoperative complications were reported, including one eye with panophthalmitis. At last follow-up (ranging from 1 day to longer than 1 year), 88% of the horses were visual.\textsuperscript{16} One horse was operated on for a morgagnian cataract and had useful vision at 7 months postoperatively.\textsuperscript{17} Despite the lack of postoperative visual correction, horses have useful vision after successful surgery. Working horses such as roping horses or polo ponies are able to work as well as they had before the development of cataracts. In foals, vision is more difficult to evaluate, but foals with congenital cataracts should probably be operated on as soon as possible to allow visual pathway development. Equine research in this area has not been conducted, but work in cats shows that visual deprivation in kittens between the ages of 4 to 12 weeks leads to abnormalities in the development of the visual pathway and behavioral blindness.\textsuperscript{18} In visually deprived humans, the same signs are seen. The critical period in humans begins soon after birth and ends in the 3rd year.\textsuperscript{19}

**Pseudophakia**
Pseudophakia is the replacement of the cataractous lens with a synthetic intraocular lens (IOL). The normal lens in a human supplies about a third of the total refractive power of the eye; lenses in animals also supply a good deal of the refractive power of the eye. Removing this lens, without implanting an IOL, would leave the patient with greatly reduced visual acuity. Therefore, IOLs are commonly implanted in people and dogs after cataract removal, with the goal providing emmetropia (the rays of light entering the eye are all brought in focus on the retina; 0D or 20/20 in the United States). Streak retinoscopy is a method of determining the focusing ability of the eye without having subjective responses from the patient (i.e., without the patient reading an eye chart). Streak retinoscopy of three aphakic equine eyes gave a mean value of +9.94D (hyperopia [far-sightedness]), whereas normal horse refraction was +0.25D (close to emmetropia).\textsuperscript{14} A pilot study using donated horses with cataracts investigated a prototype IOL of +25D. In that study, two eyes with clear media were refracted at –4.75D and –9.3D (myopia [near-sightedness]). Clearly, this +25D IOL did not allow the horses to be emmetropic, but the assumption is that decreasing the power of this IOL would lead to an emmetropic eye. However, because of intraoperative and postoperative complications associated with the large limbal incision, IOLs are presently not implanted in horses. Further work is needed to optimize lens power, and perhaps an injectable lens will be devised for the horse in the future.

**Traumatic Lens Rupture**
Perforating injuries occasionally involve the lens. If the capsular laceration of the lens is small, it can seal with only a small opacity developing in the injured area. If the laceration is large, aqueous humor can enter the lens, causing a very rapidly developing cataract. The uveitis seen with a very rapidly developing cataract. The uveitis seen with a large laceration is unresponsive to medication, probably because of the large amount of foreign protein that continues to be presented to the immune system. As in other species, the treatment of choice is lens removal. The lens should be removed as soon after the injury as possible. All injuries of this type carry a guarded prognosis.

In a series of seven horses with penetrating corneal and lenticular trauma, most eyes were enucleated.\textsuperscript{20} In one eye with an acute history, removal of the lens using phacofragmentation was performed, but the eye remained blind after surgery as a result of retinal detachment.\textsuperscript{20}

Spontaneous lens rupture is also seen. In one case seen at the authors’ clinic, a ruptured lens of several months’ duration was discovered ultrasonographically in a quiet eye with a cataract, during a cataract workup. Unfortunately, the horse was lost to follow-up.

**Vitreous and Retina**
Most retinal detachments in horses develop secondary to equine recurrent uveitis, and these are not amenable to surgical therapy. Treatment of rhegmatogenous detachments (detachments with a retinal tear) has not been described in the horse. Chapter 62 has more information on vitreal surgery and vitreal and suprachoroidal cyclosporine implants for treating recurrent uveitis.

**Glaucoma**
Although glaucoma in horses is uncommon, this condition is as difficult to treat in this species as in any other. Normal intraocular pressure in horses is similar to that in other
species and should be less than 30 mm Hg. Application
tomometers are easiest to use in this species. Both the
Nd:YAG15,21 and diode lasers22 have been used successfully
in horses to reduce intraocular pressure. Fifty-five applica-
tions of the Nd:YAG laser 5 to 6 mm from the limbus with
10 W for a duration of 0.4 second per site have been
recommended.15 For the diode laser, 1500 mW and 1500
msec per site has been described, varying from 30 to 80 sites
at 4 to 6 mm from the limbus.15
Filtration gonioimplants have been used successfully
by the author as well as by others15 to improve aqueous
outflow. The Nd:YAG15,21 and diode lasers22 have been used successfully
in horses to reduce intraocular pressure. Fifty-five applica-
tions of the Nd:YAG laser 5 to 6 mm from the limbus with
10 W for a duration of 0.4 second per site have been
recommended.15 For the diode laser, 1500 mW and 1500
msec per site has been described, varying from 30 to 80 sites
at 4 to 6 mm from the limbus.15

Intraocular Prostheses
An intraocular prosthesis can be useful for horses with
blind, painful eyes, such as eyes affected with equine recurrent
uveitis or glaucoma (see Chapter 63).

surgical management of equine recurrent uveitis

Brian C. Gilger
Bernhard M. Spiess
Equine recurrent uveitis (ERU), also known as moon blindness, iridocyclitis, and periodic ophthalmia, is one of the most common causes of blindness in horses. This immune-mediated pan-uveitis has an approximately 2% prevalence in horses in the United States. ERU is characterized by episodes of intraocular inflammation that develop weeks to months after an initial uveitis episode. Not every case of uveitis is ERU, but instead, ERU is a syndrome of chronic recurrent uveitis that differs from primary uveitis. ERU is diagnosed only when typical clinical signs of uveitis are coupled with a documented history of recurrence of inflammation. Therefore, ERU cannot be diagnosed after a single episode of inflammation.

Typical clinical signs of active uveitis include blepharospasm, epiphora, and photophobia. There is corneal edema...
and aqueous humor flare and fibrin accumulation. The pupil is usually miotic. After recurrent episodes, posterior synechiae and dyscoria may be noted. Ocular hypotony may be palpated or assessed by applanation tonometry. If the pupil can be pharmacologically dilated, capsular and subcapsular cataracts may be seen. Vitreal opacities and peripapillary chorioretinal scars are additional clinical signs. The diagnosis of uveitis is based on clinical signs and ocular hypotony.

Medications typically used to treat ERU (i.e., corticosteroids, mydriatics, and nonsteroidal anti-inflammatory drugs [NSAIDs]) are used to reduce inflammation and minimize permanent ocular damage at each episode of active uveitis, but they are not effective in preventing recurrence of disease. Corticosteroids are used topically or subconjunctivally, together with topical 1% atropine sulfate. NSAIDs are usually administered systemically. Intracameral injection of tissue plasminogen activator may be used to dissolve organized fibrinous exudates in the anterior chamber. Other medications, such as aspirin, phenylbutazone, and various herbal treatments, used by some clinicians to possibly prevent or decrease the severity of recurrent episodes of uveitis, have limited efficacy and potentially detrimental side effects when used chronically in the horse.

Cyclosporine sustained-release devices and pars plana vitrectomy offer new and promising avenues for long-term control of equine recurrent uveitis. In this chapter, treatment of recurrent ophthalmia with the help of these novel techniques is described.

## SUSTAINED-RELEASE MEDICATION DEVICES FOR ERU

Ocular devices that provide sustained release of medications have many advantages over more traditional methods of drug administration to the eye.1 These include the delivery of a constant therapeutic level of medication directly to the site of inflammation, bypassing some of the blood–ocular barriers, and eliminating the need to rely on the owners to treat their horses. Release rates are typically well below toxic levels of the drug, and higher concentrations of the drug are achieved in the eye while systemic side effects are avoided. Devices also have the benefit of being more convenient for the patient and reducing the risk involved with frequent intravitreal or periocular injections.

Cyclosporine A (CsA) is a 1.2-kD cyclic peptide that blocks the transcription of interleukin (IL)-2 and the responsiveness of the T-cell.2–4 It may be the ideal drug to prevent the activation of T-lymphocytes and the recurrence of uveitis. Because CsA is hydrophobic and does not penetrate into the eye when applied topically, currently available methods of delivery to the eye are inadequate.4–6 The pharmacokinetics of oral cyclosporine have not been determined in horses, but systemic treatment with cyclosporine may promote serious side effects such as renal, hepatic, and neurologic toxicity.7 Also, it is very costly to administer to a horse.

### Intravitreal Cyclosporine Devices

A polyvinyl alcohol and silicone–coated intravitreal CsA sustained-delivery device was shown to produce a sustained level of CsA in ocular tissues of rabbits.8,9 Similar intravitreal CsA devices (Fig. 62-1) were implanted into normal horse eyes for up to 1 year and were not associated with ocular inflammation or complications.10 In equine eyes with experimentally induced uveitis, eyes with CsA-releasing devices decreased the duration and severity of inflammation, cellular infiltration, tissue destruction, and level of transcription of proinflammatory cytokines.9 In a study using CsA devices in horses with naturally occurring ERU,11 horses with frequent recurrence of uveitis without vision-threatening ocular changes (e.g., cataracts, retinal degeneration) or systemic illnesses were selected to receive the device. Although the device prevented the development of recurrent episodes in 81% of horses, complications were noted after surgery that included intraocular hemorrhage, progression of cataract formation, and retinal detachment.12 The surgical intervention in fragile equine eyes was thought to be the source of the observed complications, so less invasive methods were evaluated for the constant release of cyclosporine.

### Suprachoroidal Cyclosporine Devices

A new device that allowed constant release of cyclosporine (or other selected immunosuppressive medications) was developed to be placed in the suprachoroidal space directly adjacent to the ciliary body (Fig. 62-2). Horses with chronic, documented ERU as determined after complete ophthalmic examination, and that have little or no active inflammation but are experiencing frequent recurrences or early relapse of active ERU after stopping medications were considered appropriate candidates for surgical placement of a suprachoroidal CsA device. Horses whose actively inflamed eyes could not be controlled with anti-inflammatory medications were not considered good candidates for CsA implantation because CsA has poor anti-inflammatory properties (its immunosuppressive properties help prevent new recurrent episodes), and inflamed eyes were considered to

![Figure 62-1. Silicone-coated pellet of cyclosporine A used for intravitreal placement for the control of equine recurrent uveitis.](image-url)
be more prone to surgical and postsurgical complications. Equine patients with evidence of significant cataract formation or other ocular conditions (e.g., glaucoma) were also considered poor candidates for surgery. *Leptospira* titers should be performed in endemic areas, and systemic antibiotic therapy (e.g., doxycycline, 10 to 20 mg/kg PO BID for 30 days) should be administered prior to considering surgical therapy for ERU.

The surgical technique for suprachoroidal device implantation requires that the horse be placed under general anesthesia. A 1-cm conjunctival incision is made in the dorsolateral bulbar conjunctiva. A 7-mm-wide scleral flap is prepared, exposing the uveal tract (i.e., the black uvea is visible) approximately 8 mm posterior to the limbus and just lateral to the insertion of the dorsal rectus muscle (Fig. 62-3). The CsA-containing device is placed into the incision, in contact with the uveal tract (Fig. 62-4). The incision is closed with the scleral flap over the implant using 5-0 to 6-0 polyglactin 910 or similar absorbable suture material in a simple-interrupted pattern (Fig. 62-5). Recommended postoperative medications include flunixin meglumine (500 mg PO once a day) for 5 days, topical triple antibiotic ophthalmic ointment BID for 10 days, and topical atropine ointment SID for 7 days. A few horses were noted to have a mild flare-up following discontinuation of the flunixin meglumine, so additional systemic anti-inflammatory medication may be needed after 5 days.

Preliminary results from a clinical trial of over 100 horses with documented ERU suggest that it takes 30 to 45 days after implantation of the device to get adequate ocular levels of CsA. Approximately 75% of horses have had complete control of the uveitis 30 days after implantation. If recurrent episodes occur after implantation, traditional treatment with systemic NSAIDs, topical steroids, and atropine is recommended. Those horses that had recurrences of the uveitis, subjectively, required less medication to control the active inflammation, and the duration of their inflammatory episodes was shorter. More important, the suprachoroidal implant is not associated with any vision-threatening complications such as retinal detachment. The duration of delivery of medication from the current devices is approximately 24 to 30 months. Evaluation of the results from a multicenter clinical trial is currently underway; if the results are favorable, approval by the U.S. Food and Drug Administration and commercial manufacture of the device will follow. A similar device is being tested for effectiveness for chronic control of canine keratoconjunctivitis sicca. Other immunosuppressive medications may also be evaluated in similar devices, such as tacrolimus (FK506), sirolimus, and rapamycin.\textsuperscript{13,14}

PARS PLANA VITRECTOMY
For more than 25 years, pars plana vitrectomy (PPV)15 has
been used in the management of chronic endogenous
uveitis (CEU) in humans.16-20 The main goal was to improve
vision by clearing the media or removing membranes.
However, it turned out that PPV in eyes with CEU also
altered or diminished the severity as well as the frequency of
attacks.18 There is evidence that PPV has a beneficial effect
on the clinical course of chronic endogenous posterior
uveitis, possibly by physically removing any resident inflam-
matory cells with the vitreous.21 Despite the reported com-
lications (i.e., vitreal hemorrhage, cataract formation,
etinal detachment) after PPV, an overwhelming majority of
the patients were able to be switched from rigorous systemic
preoperative medication to simple eye drops or no

Vitrectomy has been studied in experimental, protein-
induced uveitis in rabbits,22,23 but it was not until 1991 that
PPV has been described in the management of equine recur-
rent uveitis.24 PPV has since been increasingly employed in
the treatment of ERU in Europe.25,26 Similar to in humans,
the most common complications reported in horses are
temporary hypopyon, vitreal or retinal hemorrhage, retinal
detachment, and cataract formation.

In the majority of reported cases in Europe, Leptospira
species have been identified in serum and diluted vitreous
samples. This indicates that ERU is probably often a sequel
of systemic Leptospira infection. The presence of intact
Leptospira and specific antibodies in eyes affected with ERU
indicates a local antibody production to Leptospira organ-
isms and/or their antigens.27-30

Patient Selection
Because of the possible serious complications of PPV,
patient selection is of great importance. All patients are
examined by slit-lamp biomicroscopy, indirect and direct
ophthalmoscopy, and applanation tonometry. Ultrasonogra-
phy is performed in cases with opaque media. The
Diagnosis of ERU is based on the typical signs of acute
or chronic uveitis and a documented history of recurrent
episodes of acute uveitis. Horses ideally are operated in the
quiescent stage of the disease. Because of the transpupillary
visualization of the vitrectomy probe during the procedure,
the optical media (i.e., cornea, anterior chamber, lens)
should be as transparent as possible. The pupil should dilate
maximally with no or few posterior synechiae. Preexisting
focal cataracts are likely to progress after PPV. This should
be taken into consideration. In patients with secondary
glaucoma, phthisis bulbi, or preexisting retinal detachment,
PPV should not be recommended. Owners should be care-
fully informed about the surgery, and in particular about the
possible intraoperative and postoperative complications.

Preoperative and Postoperative Medication
Topical 0.1% dexamethasone drops in combination with
neomycin and polymyxin B are administered QID begin-
ning 1 week prior to surgery. Systemic NSAIDs (e.g.,
vedaprofen, flunixin meglumine) are administered begin-
ning 3 days preoperatively.

The pupil is dilated with 1% atropine drops on the day of
surgery.

Postoperatively, topical dexamethasone/neomycin/poly-
myxin B eye drops are continued 3 days a week for 2 weeks
and then tapered over another 4 weeks.

Systemic NSAIDs are continued for 1 week.

Surgical Technique
A standard two-port PPV is performed in lateral recumbency
under general inhalation anesthesia. The eye is prepared for
intraocular surgery. After draping, an eyelid speculum is
inserted. A lateral canthotomy may improve exposure of the
lobe. With a special manipulator, the globe is rotated to
expose the dorsal bulbar conjunctiva. Alternatively, a limbal
stay-suture may help globe manipulation. A limbal-based
conjunctival flap is prepared and the sclera exposed
medially and laterally to the dorsal rectus muscle. Using a
CO2 laser, a sclerotomy is performed 10 mm posterior to
the limbus. A right-handed surgeon places this first entry to
the left of the rectus muscle. The irrigation port is inserted
and secured to the sclera with a 4-0 polyglactin 910 suture
(Fig. 62-6). With the vitrectomy unit in continuous
irrigation mode and the fluid-containing bottle positioned
85 cm higher than the surgical site, the intraocular pressure
will be around 40 mm Hg. Physiologic saline solution
with 40 mg of gentamicin added per 500 mL is used as
irrigation fluid. A second laser sclerotomy is performed,
again 10 mm posterior to the limbus and to the right of the
rectus muscle (Fig. 62-7). The vitrectomy probe is carefully
inserted and advanced in the direction of the center of the
vitreous. The sclerotomy may be enlarged with a lacrimal
dilator if necessary. Care is taken to avoid touching the lens
when inserting the probe (Fig. 62-8). The probe tip should
be held with the aspiration port facing the surgeon. In
this position, the port can be visualized through the pupil
using the light of an indirect binocular ophthalmoscope
(Fig. 62-9).
With a 20D lens in the left hand and the vitrectomy probe in the right, vitrectomy is started. Aspiration of vitreous can easily be seen. Again, care is taken to avoid the lens. Estimating the distance between the probe and its shadow cast onto the retina helps the surgeon avoid touching the retina. Throughout the entire procedure, the intraocular pressure (IOP) should be maintained at approximately 40 mm Hg. Slight wrinkling of the retina, seen with the aid of the ophthalmoscope, indicates that the IOP may be too low. Vitrectomy should be interrupted until a normal IOP is restored. The procedure is continued until all turbid vitreal material has been removed. Under continuous irrigation, the vitrectomy probe is removed and the sclerotomy closed with one or two pre-placed simple interrupted sutures using 4-0 polyglactin 910. Subsequently, the irrigation port is removed. Remaining vitreous will usually prevent fluid from escaping through this sclerotomy, which is closed with 4-0 polyglactin 910. The conjunctiva is closed with polyglactin 910 in a continuous pattern. The canthotomy is closed with a figure-of-eight suture using 4-0 nonabsorbable suture materials.

At the end of surgery, 20 mg of methylprednisolone is injected subconjunctivally into the inferior bulbar conjunctiva.

**Technical Aspects**

To avoid uveal hemorrhage both sclerotomies are performed using a CO₂ laser in continuous mode at 50 W. Commercially available vitrectomy probes are too short for use in horses. A custom-made 55-mm oscillating vitrectomy probe is used at 6.5 Hz, at an aspiration vacuum of 240 mm Hg, and at a flow rate of 20 mL/min (Fig. 62-10). A custom-made globe manipulator is used to position the globe (Fig. 62-11).
Complications

Intraoperative complications include vitreal/retinal hemorrhage and retinal detachment. Maintaining IOP at around 40 mm Hg and using a CO2 laser for the sclerotomies instead of surgical blades can avoid hemorrhage. Touching the retina should also be avoided as it results in immediate hemorrhage and subsequent detachment.24-26

Early postoperative complications (less than 3 months) include cataract formation and retinal detachment. Late complications occurring after 3 months include cataract formation as well as recurrence of active uveitis.21,26

Long-term Results

In one study of 38 cases, five eyes showed recurrence of uveitis between 10 days and 3 years postoperatively.26 Thirty-three eyes showed no recurrence during a follow-up period of up to 5 years. Vision remained stable in 28 eyes and improved in one eye. The remaining eyes showed marked vision loss as a result of cataracts (3), phthisis bulbi (1), or unknown causes (1). Of the five eyes with recurrent uveitis two demonstrated marked loss of vision, and three maintained preoperative vision.

In an earlier study of 43 eyes after PPV, 42 remained free of recurrent uveitis after PPV. However, a significant number of postoperative complications cause visual impairment or blindness. The most common long-term postoperative complication appears to be cataract formation. It is unclear whether preexisting lenticular opacities progress despite PPV or whether the progression is caused by the procedure. Touching the posterior lens capsule during PPV invariably leads to focal cataracts, which very often progress.

Retinal and vitreal hemorrhage is the most common intraoperative complication. Maintaining a high normal IOP, careful manipulation of the vitrectomy probe, and avoidance of touching the retina usually prevents such complications. Choroidal hemorrhage can be avoided with the use of a CO2 laser instead of a surgical blade.

ANATOMY AND PHYSIOLOGY

The diagnosis and treatment of soft tissue and osseous orbital disease in the horse requires a clear understanding of the normal equine globe and orbital anatomy. The adult equine orbit is 62.1 mm in width, 59.4 mm in height, and 98.3 mm in depth. The globe of the equine eye is larger in the horizontal (48.4 mm) than in the vertical (47.6 mm) diameter. The mean anterior-to-posterior diameter is 43.7 mm. The volume of the equine globe ranges between 45.0 and 50.9 mL. The orbits and globes of the horse skull are directed anteriorly, slightly dorsally, and are positioned 80 degrees lateral to the midline to allow wide panoramic vision. The orbits are bony cavities formed by the frontal, lacrimal, zygomatic, temporal, sphenoid, and palatine bones, and they function to protect the globe. The orbits of the horse are open anteriorly and closed posteriorly, they possess a soft tissue-covered ventral floor, and they contain osseous canals, fissures, and foramina. Sinuses surround the orbit.

The anterior rim of the bony orbit is complete in the horse (see Fig. 63-1). The nasal wall is extensive and formed by the frontal, lacrimal, and presphenoid bones. The roof or dorsal wall is formed by the frontal and, to a small degree, the lacrimal bone. The orbital floor or ventral wall consists anteriorly of the zygomatic bone and the zygomatic process of the frontal bone and the orbital foramen including ethmoid, optic, orbital fissure, and rostral alar. S, sphenoid bone; SF, supraorbital foramen; T, temporal bone; Z, zygomatic bone; ZPF, zygomatic process of the frontal bone; ZPT, zygomatic process of the temporal bone.

Figure 63-1. A normal skull, demonstrating the complete anterior bony orbital rim of the horse. The pertinent bones that form the orbit of the horse are labeled: LAC, lacrimal bone; OF, orbital foramina including ethmoid, optic, orbital fissure, and rostral alar; S, sphenoid bone; SF, supraorbital foramen; T, temporal bone; Z, zygomatic bone; ZPF, zygomatic process of the frontal bone; ZPT, zygomatic process of the temporal bone.
process of the temporal bone, with the larger posterior orbital floor consisting of soft tissue formed by periorbital fascia. The zygomatic arch, formed by the zygomatic process of the frontal bone, the frontal process of the zygomatic bone, and the zygomatic process of the temporal bone, closes the temporal orbital wall. Trauma to the prominent zygomatic arch of the horse skull may result in severe skin lacerations because the anterior edge of the zygomatic arch facial crest is quite sharp.

The zygomatic process of the frontal bone contains the supraorbital foramen, which carries sensory nerve fibers to the upper eyelid. The lacrimal bone forms the nasal part of the anterior orbital rim. The anterior ventral surface contains the entrance to the lacrimal canal, and it is the site of origin for the ventral oblique muscle. The sphenoid bones form the nasal, posterior, and ventral orbital boundaries. The optic nerve and internal ophthalmic artery pass in the optic canal of the presphenoid bone and enter the orbit at the optic foramen. The basiethmoid bone is associated with the orbital and round foramina, the alar canal, the maxillary and nerve, and the cavernous sinus.

The extreme posterior orbit contains the ethmoidal vessels and nerve, the optic foramen with the optic nerve and internal ophthalmic artery, the orbital foramen with cranial nerves III through VI, the round foramen and the maxillary nerve, and the rostral alar foramen with the external ophthalmic and maxillary arteries. The maxillary, sphenopalatine, and major palatine foramina and their associated blood vessels and nerves are found ventral to the anterior portion of the orbital cavity in the pterygopalatine fossa.

The orbit system functions as a precise and complex unit. An extensive system of orbital connective tissues forms a framework for the compartmentalization and support of all orbital structures to maintain appropriate anatomic relationships and to allow the precise and coordinated globe movements. The essential components of the orbital connective tissues are the peri orbits, the orbital septum, and the episcleral fascia or Tenon’s capsule.

Periosteum lines the orbital bones and the optic and orbital foramina. Attached to the surface of the periosteum are multiple layers of orbital connective tissue called the periorbita. The inner layers of the periorbita continue anteriorly as the orbital septum, which separates from the periosteum at the lid margin to continue into the lid as the tarsal plate. The optic nerve is contained within a dural sheath that is continuous at the orbital apex with the periosteum of the optic canal. Well-developed fascial slings of the orbital septum form suspensory complexes with orbital fat to maintain precise extraocular muscle alignment as the globe moves. Tenon’s capsule, also termed episcleral fascia, is located between the conjunctiva and sclera. Tenon’s capsule begins anteriorly at the perilimbral sclera and extends around the globe to the optic nerve, where it blends with fibers of the dural sheath and sclera. It is firmly adherent to the episcleral tissue anterior to the scleral insertions of the rectus muscles.

The frontal sinus is located dorsal and ventral to the medial orbit. The maxillary sinus is located ventral and nasal to the orbit. The bony plate between the orbit and maxillary sinus is very thin. The anterior maxillary sinus can be located just ventral to the intersection of (1) a line between the medial canthus and infraorbital foramen and (2) a perpendicular line from the fourth cheek tooth. Trephination dorsal to a line drawn between the infraorbital foramen and the medial canthus may result in nasolacrimal duct damage (see Chapter 42). The center of a line drawn between the medial canthus and the facial crest indicates the location of the caudal maxillary sinus. The sphenopalatine sinus is located medial and ventral to the orbit. All sinuses in the horse communicate with the nasal cavity either directly or via the maxillary sinus. In horses, sinus disease involving the frontal, maxillary, or sphenopalatine sinuses may intrude on the orbit.

The lacrimal gland, orbital fat, and connective tissue fascia completely fill the orbital spaces between the globe, extraocular muscles, optic and other cranial nerves, and orbital vascular elements of horses to provide a cushion that protects these delicate structures from injury during ocular movements. The lacrimal gland is situated dorsolaterally between the zygomatic process and the globe. It is separated from the globe by periorbital fascia, and it opens via 12 to 16 small ducts along the lateral part of the conjunctival sac in a line anterior to the dorsal conjunctival fornix. Care should be taken when preparing conjunctival flaps or when placing subpalpebral lavage systems in this area, since damage to these ducts could result in a tear insufficiency problem. There is no orbital salivary gland in the horse. A cushion of fat lies in the ventral equine orbit.

The horse has seven extraocular muscles. The dorsal rectus muscle rotates the globe dorsally, and the ventral rectus muscle rotates the globe ventrally. The medial and lateral rectus muscles rotate the eye medially and laterally, respectively. The dorsal oblique muscle rotates the dorsal part of the eye medially and ventrally along an anterior–posterior axis, and the ventral oblique muscle rotates the ventral part of the eye medially and dorsally. The retractor bulb muscle pulls the globe into the orbit to allow passive movement of the nictitating membrane to protect the globe. All extraocular muscles except the ventral oblique arise near the optic foramen. The sites of scleral insertion of the equine extraocular muscles are listed in Table 63-1. The oculomotor nerve innervates the ventral oblique muscle and the dorsal, ventral, and medial rectus muscles. The abducens nerve innervates the lateral rectus and retractor bulbi muscles. The trochlear nerve innervates the dorsal oblique muscle.

**PATHOPHYSIOLOGY**

Orbital disease processes may occur within the extraocular muscle cone (intraconal), between the muscle cone and the periocular sheath, or external to the periocular sheath (subperiosteal). Orbital diseases can result in exophthalmos caused by space-occupying orbital lesions, or in enophthalmos if the volume of the orbital contents becomes reduced as a result of malnutrition or disease. The degree and direction of exophthalmos depends on the size and location of the lesion. Intraconal lesions cause anterior displacement of the globe. Lesions of the medial orbit displace the globe laterally. Exposure keratitis may result because of the inability of the lids to cover the cornea in a severe case of exophthalmos. Large space-occupying masses such as tumors or bone fragments can limit ocular motility.
and impair ocular circulation. The globe size of the exophthalmic eye is normal and should not be confused with the globe enlargement (buphthalmos) noted in advanced equine glaucoma. The nictitating membrane may protrude with exophthalmos or enophthalmos.

Infectious, traumatic, inflammatory, or neoplastic disease processes involving the eyelids, paranasal sinuses, tooth roots, guttural pouch, or nasal cavity may extend into the orbit to cause exophthalmos. Fractures of the walls of the paranasal sinuses and orbit can result in enophthalmos, facial deformity, and orbital emphysema. Tooth root abscesses may cause sinus and orbital disease.

**DIAGNOSTIC PROCEDURES**

The diagnosis of orbital disease may require special diagnostic procedures in addition to a complete ophthalmic examination.

**Retrobulbar Needle Aspiration**

Aspiration of fluid or biopsy of a mass behind the globe should be performed for culture, cytology and/or histopathology for differentiation of space occupying masses in cases of exophthalmos (Fig. 63-2). An 18-gauge, 10-cm, slightly curved needle is inserted 1 cm lateral to the lateral canthus and directed posteriorly in a line parallel to the medial canthus. Care is taken to prevent damage to the globe or optic nerve. This technique may be varied in selected cases by making a small skin incision and obtaining a large-needle core biopsy from the supraorbital fossa behind the globe.

**Retrobulbar Nerve Blocks**

Orbital or retrobulbar anesthesia can reduce eye and third eyelid movement, and it can decrease corneal sensation for short ophthalmic procedures such as eyelid laceration repair, nictitans removal, corneal foreign body removal, intraocular injections or aqueocentesis, or iris cyst laser ablation in standing horses and horses under general anesthesia. Retrobulbar nerve blocks can reduce the depth of general anesthesia required for enucleation surgery. A 22-gauge, 6.25-cm spinal needle is inserted through the skin prepared for aseptic surgery of the orbital fossa, just caudal to the posterior aspect of the bony dorsal orbital rim. The needle is advanced until it reaches the retrobulbar muscle cone. This can be detected by slight dorsal movement of the eye. Once positioned, 10 to 12 mL of 2% lidocaine is injected into the orbit. Slight exophthalmos occurs. The lidocaine takes effect in 5 minutes and lasts 1 to 2 hours.

Radiography

Radiography is especially useful in fracture localization and diseases associated with bony destruction. Meticulous attention to detail in film handling and patient positioning, and a thorough knowledge of normal equine orbital anatomy are required for radiographic examination of the horse with signs of orbital disease. Good-quality films can be obtained with portable radiographic equipment and rare earth screens.

Radiographs should be taken using lateral, ventrodorsal, oblique, and dorsoventral views to attempt to identify ocular and orbital foreign bodies, tumors, fractures, or the extent of soft tissue or bony lesions (Fig. 63-3). Oblique views should be oriented to silhouette the area of greatest soft tissue swelling, with a contralateral (normal) oblique view used for comparison. Special attention should be directed to examination of the nasal cavity, paranasal sinuses, tooth roots and calvarium. Dorsoventral views reveal nasal cavity or bony nasolacrimal duct problems. In the evaluation of unilateral lesions, the involved portion should be placed against the film cassette. Most lateral, dorsoventral, and oblique views of the equine orbit can be obtained with the use of xylazine sedation. Ventrodorsal views of the orbit require general anesthesia. A Flieringa ring placed at the limbus can help localize the globe and orbit. Orbital aspirates and biopsies may be performed after the radiographic study of the orbital region so as not to introduce artifactual changes into the radiographic image. The reader might want to review the normal radiographic orbital anatomy of the horse.23

The multiple superimposed bones, teeth, soft tissue, and air shadows in a skull radiograph of a horse may initially appear to be nothing more than a confusing mass of shadows. Increased soft tissue densities and lytic bone changes are associated with neoplasia and chronic inflammatory diseases. Calcification of soft tissues may develop as a result of orbital cellulitis and tumors.

The advent of high-resolution computed tomography (CT) and magnetic resonance imaging (MRI) has dramatically enhanced orbital evaluation in humans and small animals, and it is the procedure of choice in these species.24,25 In the horse, CT and MRI are more limited because of the ratio of the size of the animal to size of the imaging units.18,24 Foals can be easily evaluated by these methods. Utilization of these techniques in equine ophthalmology continues to increase (Fig. 63-4).

Ultrasonography

Ocular ultrasonography is a noninvasive diagnostic procedure that can qualitatively and quantitatively evaluate various globe and orbital abnormalities. It is indicated for evaluation of an exophthalmic globe or a globe obscured by opacities of the cornea, lens, or vitreous.25,26 Differentiation...
of solid soft orbital tissue masses versus cystic orbital masses (Fig. 63-5), determination of the size of various globe or orbital components, and localization of orbital foreign bodies are possible. Real time B-scan ultrasound units emit focused sound waves to produce a two-dimensional cross-section of orbital tissues, with ultrasound probes of 7.5 or 10 MHz providing the best resolution. The ultrasonic transducer can be placed in contact with the eyelids via a methylcellulose coupling agent to evaluate the globe and anterior orbit, or it can be placed in gentle contact with the cornea after instillation of a topical anesthetic to evaluate the posterior orbit. For the evaluation of the orbital structures, the ultrasonic beam is angled so that it enters the orbit between the globe and the bony orbital wall. This bypasses the lens, which tends to attenuate the sound beam and maximizes the echo intensity. Most orbital lesions exhibit lower reflectivity and less sound attenuation than the normal orbital contents. Foreign bodies are hyperechoic in many cases. The opposite globe and orbit provide a normal “control” for comparison purposes (see Fig. 63-5, C).

Figure 63-5. A, B-scan ultrasonographic view reveals an orbital optic nerve tumor (arrow). B, This ultrasonographic scan reveals a retinal detachment that resulted from severe eye trauma (arrows). The vitreous is opaque from hemorrhage. C, A normal B-scan ultrasonographic image is shown for comparison.
SURGICAL TECHNIQUES

The instruments used for orbital surgeries such as enucleation, exenteration, and evisceration (Fig. 63-6) are the standard instruments utilized for soft tissue surgeries. Some magnification via head loupe is helpful. If the zygomatic arch or other orbital bones need to be removed, osteotomes, an oscillating bone saw, and pneumatic drill are required.

Exenteration

Indication and Surgical Technique

Orbital exenteration is a surgical technique used to remove large malignant tumors of the orbit that are unresponsive to chemotherapy or radiotherapy. In this procedure, the entire orbital contents, including periobitor and globe, are surgically removed. The eyeball or globe is enucleated first (see Fig. 63-6, A). Periosteal elevators may be needed to remove the periorbital fascia. The remaining tissue is excised using scalp or scissors. Bleeding is controlled with ligature and cautery. A skin graft can be used to cover the open socket if excessive eyelid skin must be removed, or the socket can be left to granulate and epithelialize in rare cases. A permanent tarsorrhaphy is performed to cover the orbital cavity if the lids were not involved in the disease process.

Aftercare

Postoperative care should include pressure dressings on the head to reduce swelling and the use of a tamponade if hemorrhage was severe. Systemic antibiotics and non-steroidal anti-inflammatory agents are indicated. Inadvertent entry into a paranasal sinus may require trephination of the sinus, lavage, and drainage.

Evisceration

Evisceration refers to surgical removal of the iris, lens, ciliary body, choroids, vitreous and retina. The cornea, the sclera, and their extraocular muscle attachments are left intact. This is performed prior to placement of an intrascleral silicone implant or a prosthesis. Evisceration is not generally recommended for an eye suspected of having an intraocular tumor or infection, or for eyes with severe corneal disease. Horses beginning to undergo globe atrophy or phthisis bulbi are good candidates. This surgery is performed mainly for cosmetic purposes.

Surgical Procedure

A 180-degree limbal peritomy is performed with tenotomy scissors. The conjunctiva is then undermined so that the sclera near the limbus is free of conjunctiva and fascia. A no. 15 blade is used to make a 180-degree full-thickness incision in the sclera 4 to 5 mm from the limbus. Suction and cautery are used to control extensive hemorrhage and visualize the incision. A lens loop or evisceration spoon is used to remove all the intraocular contents while the globe is fixed with toothed forceps. Care is taken to avoid scraping the corneal endothelium. A silicone implant of suitable size (usually 34 to 44 mm) is inserted into the sclera so that sutureing the sclera can be accomplished without undue tension. Preoperative ultrasonic measurement of the normal eye aids in the selection of the proper-size implant. The anterior face of the implant can be trimmed to create a flatter surface in the part of the implant that is apposed to the cornea. Simple-interrupted sutures of 6-0 absorbable suture are placed in the sclera, and a simple-continuous pattern of 6-0 absorbable suture is placed in the conjunctiva.

Aftercare

Topically applied antibiotics and systemically administered antibiotics and non-steroidal anti-inflammatory agents should be used postoperatively. A temporary tarsorrhaphy protects the cornea while postoperative eyelid swelling subsides.

Complications

The main complications are extrusion of the implant as a result of rubbing of the head, and postoperative infection. Enucleation is the only recourse if these occur. Protective headgear helps prevent irritation from head rubbing. Placement of too small an implant results in a cosmetically unacceptable eye. Owners should be warned that corneal opacification and vascularization also may occur in some animals and cause problems with ocular cosmesis. Corneal opacification and vascularization in show horses can be masked for short times with tinted contact lenses. Healing time of intrascleral implants is typically 6 to 8 weeks.

Enucleation

Indication and Types

Enucleation refers to surgical removal of the globe, conjunctiva, and nictitating membrane because of severe corneal infection and endophthalmitis, corneal or adnexal neoplasia, orbital neoplasia, or severe ocular trauma causing a painful, blind eye. This procedure does not necessarily indicate a failure of ophthalmic care; it may be a necessary and planned treatment for specific conditions. The two basic approaches to enucleation in the horse are the transpalpebral and subconjunctival techniques. Orbital silicone implants may be placed with either method to reduce "pitting" of the eyelid skin after enucleation.

Transpalpebral Enucleation Technique

The transpalpebral technique (see Fig. 63-6, D through G) is most useful for cases of severe corneal infection, endophthalmitis, and widespread neoplasia of the conjunctiva, nictitating membrane, cornea, or orbit. It does leave a large orbital soft tissue defect. In this approach, dissection into the orbit is made external to the extraocular muscles. The conjunctiva, globe, and nictitating membrane are completely removed en masse.

The eyelids are sutured together with a simple-continuous suture and the ends held with hemostatic forceps (see Fig. 63-6, D through G). An incision 5 mm from the eyelid margin (where the skin hair begins) is made with a no. 15
Figure 63-6. The surgical techniques for enucleation (A), exenteration (B), and evisceration (C). Enucleation by the transpalpebral method involves closure of the lids, an incision around the eyelid margin, and blunt dissection posteriorly without breaking into the conjunctival sac (D through G). The subconjunctival enucleation technique (H and I) involves subconjunctival dissection posteriorly.

Continued
scalpel blade. The angularis oculi vein located near the medial canthus should be avoided. Blunt subcutaneous dissection with Metzenbaum scissors is performed posteriorly, taking care to avoid breaking into the conjunctival sac. The medial and lateral canthal ligaments are transected with the blade. A large curved Rochester-Carmalt hemostat (20 to 25 cm) or Satinsky vascular clamp (27.3 mm) is used to crush the optic nerve, and curved scissors are used to transect the optic nerve between the globe and the clamp (see Fig. 63-6, J and K). The optic nerve is best approached from the nasal side of the orbit. Care should be taken not to pull on the optic nerve, as tension at the optic chiasm may result in damage to the contralateral eye. A ligature may be placed on the transected optic nerve stump, and the nerve tissue is cauterized (see Fig. 63-6, J and K). Soft tissues of the orbit are closed in a simple-continuous pattern with 3-0 absorbable suture to minimize postoperative “pitting” of the eyelids. A silicone prosthesis can be inserted prior to closure of the muscle, fascial, and eyelid skin layers to reduce the postenucleation orbital tissue defect. Simple-interrupted sutures of 4-0 nylon or silk are used to permanently close the skin incision (see Fig. 63-6, L).

**AFTERCARE**

All enucleated globes should be submitted in fixative for histologic evaluation. Some postoperative swelling is to be expected. Slight epistaxis may occur postoperatively. Systemically administered antibiotics and nonsteroidal anti-inflammatory drugs are beneficial.

**COMPLICATIONS**

Complications of enucleation include intraoperative rupture of the globe (causing orbital contamination with microbes or tumor cells into the orbit and circulation), severe intraoperative and postoperative hemorrhage, orbital cyst formation resulting from failure to remove all secreting orbital and ocular tissues, and blindness from stretching of the contralateral optic nerve as a result of pulling on the affected optic nerve intraoperatively. Rupture of an infected eye may result in orbital infection and cellulitis. In such cases, the orbit should be irrigated with povidone-iodine solution, and intraoperative cultures should be obtained. Broad-spectrum systemic antibiotics should also be administered and the regimen modified according to the sensitivities of the organism isolated. A drain should be placed if contamination is severe. Surgical transection of the optic nerve may result in severe intraoperative hemorrhaging. Wet-field cautery or careful ligation should result in hemostasis. Metal hemoclips can also be used to control bleeding. Eyelid tamponade and head bandaging suppresses slight postoperative hemorrhaging. An orbital silicone implant should not be placed if infection or a tumor is found in the orbit at enucleation.

**Subconjunctival Enucleation Technique**

The subconjunctival approach (see Fig. 63-6, H and I) is quicker and associated with less hemorrhage. It should be used when a cosmetic shell is to be placed to maintain the integrity of the lid margin. A lateral canthotomy may be necessary to increase exposure. A 360-degree limbal peritomy is performed using sharp scissors. All four quadrants are undermined posteriorly with tenotomy or Metzenbaum scissors (see Fig. 63-6, H and I). The extraocular muscles are isolated and transected. The medial and lateral canthal ligaments are transected with a blade. Cautery is used to control bleeding.

A large, curved Rochester-Carmalt hemostat (20 to 25 cm) or Satinsky vascular clamp (27.3 mm) is used to crush the optic nerve, and curved scissors are used to transect the optic nerve between the globe and the clamp (see Fig. 63-6, J and K). The optic nerve is best approached from the nasal side of the orbit. Care should be taken not to pull on the optic nerve, as tension at the optic chiasm may result in damage to the contralateral eye. A ligature may be placed on the transected optic nerve stump, and the nerve tissue cauterized. The nictitating membrane and its gland are carefully removed with scissors. Three to 5 mm of the lid margin is excised with scissors. The conjunctiva is stripped from the remaining lid, and the subcutaneous fascia and orbital septum are closed with a simple-continuous suture pattern of 3-0 absorbable suture material to produce a tissue bridge across the front of the orbit. This minimizes postoperative eyelid “pitting.” The lid incision is permanently closed in a simple-continuous pattern with 3-0 absorbable suture to minimize postoperative “pitting.” A silicone prosthesis can be inserted prior to closure of the muscle, fascial, and eyelid skin layers to reduce the postenucleation orbital tissue defect. Simple-interrupted sutures of 4-0 nylon or silk are used to permanently close the skin incision (see Fig. 63-6, L).

**Figure 63-6, cont’d.** In both methods, the extraocular muscles are transected and the optic nerve is subsequently clamped (J and K). A two-layer skin closure is performed (L).
closed with simple-interrupted sutures of 4-0 nylon or silk. A silicone prosthesis can be inserted prior to closure of the muscle, fascia, and skin layers to reduce the orbital defect.

Prosthetic Implants

**Intrascleral Prosthetic Implants**

The intrascleral prosthesis (ISP) or intraocular silicone prosthesis has been used in horses as a cosmetic alternative to enucleation.3,9,10,27-29 The ISP replaces the intraocular contents, which are removed by evisceration. Implants of 34 to 44 mm in diameter are recommended for adult horses but, as mentioned before, should not be placed in eyes with severe corneal disease, intraocular neoplasia, or infectious panophthalmitis. The ISP provides a cosmetically acceptable, nonpainful eye that has normal lid movements, normal tear function and normal globe motility.28,29

**Intraorbital Prostheses**

Intraorbital prostheses are used to prevent severe pitting of the skin over the orbital cavity after exenteration or enucleation.3,27-29 The use of intraorbital implants in the presence of orbital neoplasia and/or infection is controversial. Implants for horses are available from Jardon Eye Prosthetics (Southfield, Mich). A silicone orbital implant specifically designed to reduce postenucleation eyelid skin “pitting” is now available from Veterinary Ophthalmic Specialties (Moscow, Idaho).

**Extrascleral Shell Prostheses**

Extrascleral shell implants or conformers consist of hydroxyapatite, porcelain, or methylmethacrylate shells made by ocularists to cover a disfigured or phthisical globe.30 The surface of the shell is painted and the prosthesis is placed into the conjunctival sac. The lids and nictitating membrane hold the conformer in place. Daily cleaning and high costs are the main limitations to their use, but the results are quite extraordinary.30 (Fig. 63-7). Ocular conformers are available from Jardon Eye Prosthetics or can be custom made for horses by Dallas Eye Prosthetics (Dallas, Tex).

**Orbitotomy**

**Indication**

Orbitotomy is indicated for biopsy or excision of orbital masses, drainage of infectious processes that are nonresponsive to medical therapy, or retrieval of foreign bodies. Orbital surgery may also be necessary in the horse to repair periorbital fractures.6,20

**Surgical Procedures**

Surgical procedures used for orbital exploration in the horse include a dorsal orbitotomy approach15,20 and approaches that require an osteotomy of the zygomatic, temporal, and frontal components of the zygomatic arch.5,16,17 The dorsal orbitotomy approach involves a slightly curved skin incision over the dorsal orbital region just lateral to the external sagittal crest of the frontal and parietal bones, extending laterally caudal to the zygomatic process of the frontal bone. Lateral retraction of the attachments of the frontoscutularis, interscutularis, and temporal muscles to the temporal and frontal bones allows exposure of the extraocular muscle cone.6

An alternative orbitotomy procedure in horses involves resection of the zygomatic, temporal, and frontal components of the zygomatic arch16,17 (Fig. 63-8). A lateral canthotomy is performed for exposure. A slightly curved skin incision is made over the length of the zygomatic process of the frontal bone, being careful to preserve the sensory nerve fibers to the upper eyelid from the supraorbital foramen and the laterally located motor fibers to the orbicularis oculi muscle from the palpebral branch of the facial nerve. The periosteum of the cranial rim of the zygomatic process is incised along its length and the aponeurosis of the frontoscutularis, interscutularis, temporal, and masseter muscles reflected. A wedge of the zygomatic process of the frontal bone is removed with an oscillating bone saw or osteotome to expose the dorsolateral orbit. The lesion is drained, or biopsied and debulked.
Iridium seeds can be implanted or cisplatin injected into the tumor mass. The bone wedge is then replaced and fixed into position with 20-gauge stainless steel wire through predrilled 2-mm holes. The periosteum and subcutaneous tissues are closed with simple-interrupted absorbable sutures. The skin incision and canthotomy are closed with simple-interrupted nonabsorbable sutures.

**SURGICAL DISORDERS OF THE ORBIT**

**Congenital Orbital Disease**

**Strabismus**

Strabismus refers to a deviation of the globe from its normal position. In the neonatal foal, the horizontal axis of the pupil and globe is deviated slightly medially and ventrally, and the eye reaches the normal adult position by 1 month of age.31 Strabismus in adult horses may be associated with visual difficulties and abnormal head posture1,10 (Fig. 63-9). Surgical correction of strabismus by rectus muscle transposition is infrequently performed in veterinary ophthalmology. Muscles can be weakened by moving the muscle insertion posteriorly, or they can be strengthened by shortening the muscle or advancing the insertion site anteriorly, or muscle insertions can be transposed to different locations to alter the functional pull of the muscles. The reader is advised to consult the literature and a veterinary or physician ophthalmologist prior to attempting correction of strabismus in the horse.

**Microphthalmos**

Microphthalmos refers to a congenitally small globe. This differs from phthisis bulbi, in which a normal-size globe degenerates because of severe injury. If microphthalmos is associated with other ocular defects, it is termed a complicated microphthalmos. If the globe is simply small and functional, it is termed a pure microphthalmos.32 The microphthalmic globe may be so small that a secondary entropion occurs, causing ulcerative keratitis and pain. Enucleation and orbital implant surgery is indicated in some cases to prevent skull deformities associated with abnormal skull growth caused by severe microphthalmos.10

**Acquired Orbital Disease**

**Orbital Cellulitis or Sinusitis**

Inflammatory, infectious, and neoplastic diseases of the sinuses and guttural pouch, teeth problems, foreign bodies, and trauma may result in orbital cellulitis or abscess formation.3,10 Orbital cellulitis is manifested by blepharohemorrhage, swelling of the supraorbital fossa, exophthalmos, orbital pain, epiphora, and nictitating membrane protrusion. Orbital cellulitis can damage the globe and optic nerve of the horse within a short time. Treatment should be timely and aggressive. Topically applied and broad-spectrum systemically administered antibiotics are always indicated. Ultrasonography and radiography may help localize the site of inflammation. Trephination into a paranasal sinus for...
culture of exudate, irrigation, and drainage is indicated if sinusitis is involved. Fluid-filled swellings should be aspirated and specimens submitted for microbiologic culture and cytology. Orbital cellulitis caused by traumatic orbital contusions may be associated with fractures of the orbital rim. Retrobulbar hemorrhage from trauma can result in exophthalmos.24

Orbital Neoplasia

Tumors reported from the equine orbit include lipoma, fibroma, paranglioma, osteoma, adenocarcinoma, lymphosarcoma, melanoma, sarcoïd, squamous cell carcinoma, meningioma, hemangiosarcoma, sarcoïd, multilobular osteoma, neurofibroma, medulloepithelioma, schwannoma, and neuroendocrine tumors.3,10-19 Progressive exophthalmos, orbital swelling, blindness, strabismus, anisocoria, and behavioral abnormalities are reported symptoms of horses with orbital tumors.3,10-19 If the tumor is extensive and the eye incapable of vision, it should be enucleated and the orbit exenterated. Intralesional iridium implantation or cisplatin chemotherapy into the orbital tumor may be beneficial in some types of neoplasia. The presence of a sighted eye and a retrobulbar mass in the horse requires that an orbitotomy be considered for diagnosis and possible therapy.*

Other Orbital Conditions

Hydatid cysts in the orbit have been reported to cause exophthalmos and optic nerve atrophy in horses in Europe.33 Fungal infections can affect the horse orbit.8 Orbital fat may herniate through weakened episcleral fascia or from trauma to cause lobular subconjunctival masses that mimic tumors.3,34 Aspiration, biopsy, and cytologic evaluation of these masses reveals the presence of adipose cells. The lesion can be simply observed, or the affected tissue can be excised and the wound sutured to prevent recurrent herniation.3,34

Traumatic Proptosis

The complete bony orbital rim of the horse protects against traumatic globe proptosis, but this problem does occasionally occur after orbital injuries.46 Miosis with severe hypotony and hyphema indicates severe trauma and has a poor prognosis for a viable globe. Corneal ulcers, corneal desiccation, and keratomalacia can be minor or severe. The horse eye tolerates little disruption of its intraocular blood supply, and severe intraocular hemorrhage usually results in phthisis bulb. The globe with proptosis should be replaced into the orbit with the horse under general anesthesia. A temporary tarsorrhaphy will protect the cornea. Topically applied antibiotics and atropine, and systemically administered nonsteroidal anti-inflammatories and antibiotics will decrease swelling and minimize infection. The globe should be reexamined when lid swelling has subsided, and the cornea and globe integrity reevaluated.

*References 3, 6, 7, 13, 15, 16.

Orbital Fractures

Fractures of the bones of the orbit (Fig. 63-10) may be manifested by asymmetry of the globes or face, epistaxis, exophthalmos, proptosis, eyelid and conjunctival swelling, depression or concavity of the periorbital region, crepitus, and sometimes pain on periorbital palpation. Damage to the intraosseous nasolacrimal duct, globe, optic nerve, or paranasal sinuses can also occur.6,20,21 All cases of suspected orbital fractures should be examined and evaluated by radiography. Ophthalmic complications include corneal ulcers, iridocyclitis, entrapment of the globe by bone fragments, and blindness.20,21

Periorbital fractures should be repaired quickly, because fibrous union of the fractured pieces begins within 1 week after the injury to make elevation and realignment very difficult.5,20 Minor orbital rim fractures seldom require surgical correction unless they are contributing to continued proptosis. Small bone fragments should be removed to prevent sequestrum formation. Bony fragments near fractures of the medial canthus can impinge and entrap the globe. Fragments may be palpated at the conjunctival fornix.20,21 Open fractures should be lavaged and debrided to remove necrotic tissues. Necrotic bone should be curetted to a bleeding surface. Surgical exploration may reveal fractures to be more extensive than were detected radiographically.20,21 Incomplete fractures may not be visible without subperiosteal dissection. Failure to repair large fractures may result in permanent facial deformity.20,21 Fracture sites should be approached by slightly curved skin incisions adjacent to the fracture site.20 Monofilament stainless steel wire suture (20- to 22-gauge), cerclage wire, small pins and orthopedic bone plates (Fig. 63-11), and cancellous bone...
grafs are utilized to stabilize bone fragments, and to immobilize and repair extensive orbital fractures.\(^6,20,21\) Fractures that are difficult to elevate may be reduced by drilling trephine holes at the fracture periphery and using angled probes to elevate the fragment (see Chapter 103). Postoperative antibiotics and nonsteroidal anti-inflammatory drugs are indicated to reduce infection, inflammation, and discomfort. Concurrent corneal ulcers, uveitis, lid lacerations, and other associated eye problems should also be treated appropriately.

CHAPTER 64

Ocular Emergencies and Trauma
Dennis E. Brooks

Many ophthalmic emergencies in the horse are related to trauma.1-5 The active physical nature of the horse in a stable, trailer, race track, or pasture environment leaves the large prominent orbit, eye, and adnexal structures vulnerable to traumatic injury. Ocular emergencies in the horse can provide some of the most challenging experiences for the veterinarian, in preserving sight, relieving pain, and restoring cosmesis. In general, any acute change in appearance, comfort, or vision of the eye should be considered an emergency. Consultation with a veterinary ophthalmologist is advisable in horses with extensive corneal disease, severe globe damage, marked orbital fractures, and periorbital soft tissue damage.2,3

Failure to look beyond the obvious when assessing the equine patient presented for ocular trauma can prevent recognition of associated subtle and concurrent eye problems.1-3 Vision is to be cherished, and it is important to initiate aggressive medical and surgical therapy of trauma-damaged horse eyes.

EVALUATION OF THE TRAUMATIZED EYE
Adequate restraint is very important in evaluating the traumatized eye of the horse. The pain may be so intense that examination or manipulation of the orbital area is difficult. The eyelids may be so swollen that the globe cannot be examined. The eyelids should never be forcibly opened, because rupture of the eye and expulsion of intraocular contents may occur through a full-thickness corneal or scleral laceration. Topically applied anesthetics, supraorbital sensory and auriculopalpebral motor nerve blocks, a nose or ear twitch, and intravenous sedation facilitate examination of the horse with a damaged eye. The fluorescein and rose bengal dye tests should be an integral part of every ocular examination of horses with traumatized eyes. General anesthesia may be necessary in some horses for thorough ophthalmic examination, and it is definitely required for the meticulous repair of many injuries of the eye and periocular region.

ORBITAL CONTUSION AND PERI-ORBITAL FRACTURES
Etiology and Diagnosis
The anterior rim of the bony orbit is complete in the horse. Orbital contents are cushioned by orbital fascia, fat, and the extraocular muscles.1-3 Periorbital fractures of the orbital rim, zygomatic arch, and supraorbital process can occur from collisions with inanimate objects, or from kicks or blows to the head.2,5 Orbital fractures can be identified by palpation, facial deformity, ultrasonography, radiography, and computed tomography. Fractures may be accompanied by blepharoedema, epistaxis, orbital emphysema, corneal ulcers, uveitis, and limitations of global motility caused by entrapment of bone fragments.1,2,5 Retrobulbar hemorrhage and cellulitis associated with orbital trauma may cause exophthalmos. Proptosis of the globe is rare but can occur after penetrating orbital injury.3

Treatment
Treatment of orbital soft tissue trauma depends on the specific ocular area damaged, the degree of dysfunction or displacement, and the involvement of adjacent orbital tissues. Systemically administered antibiotics and non-steroidal anti-inflammatory drugs are indicated to minimize infection and to reduce pain and eyelid swelling. Topically applied corticosteroids should be used only in the presence of an intact corneal epithelium. Cold compresses in acute cases and hot compresses in more chronic cases of orbital trauma may speed a reduction in eyelid swelling. Dimethyl sulfoxide can be applied topically to reduce swelling in edematous eyelids. Minor orbital rim fractures may not require surgical correction unless fracture fragments are impinging on the globe. Interosseous wiring with stainless steel suture, bone plating, and cancellous bone grafts may be necessary to immobilize and repair extensive orbital fractures.2,5

EYELID AND NICTITANS INJURIES
Etiology and Diagnosis
Eyelid lacerations are common in the horse.3 Damage to the upper eyelid is more significant, because most lid movement occurs in the upper eyelid. Medial canthal lacerations may result in damage to the nasolacrimal canaliculi. Lid lacerations may be accompanied by orbital cellulitis, periorbital fractures and bony sequestration, and severe to minor corneal ulceration. Careful examination of the globe for corneal integrity, anterior chamber clarity and depth, and scleral continuity is essential.

Treatment
Small eyelid punctures can cause an infectious retrobulbar cellulitis or abscess with fever and exophthalmos. These eyelid wounds should be cultured for bacteria and fungi, bony or other foreign bodies removed, necrotic tissue surgically débrided, and the area covered with warm compresses. Systemically administered antibiotics and nonsteroidal anti-inflammatory drugs will aid in resolving the condition. In some cases, surgical drains may need to be placed (Fig. 64-1).

Eyelid lacerations need to be repaired quickly to avoid eyelid infection, reduce eyelid edema, minimize scarring of the lid, and prevent corneal desiccation and ulceration. Small lid lacerations can be repaired under local anesthesia and mild sedation. Débridement is rarely necessary because of the abundant eyelid circulation, but when it must be
done, it should be performed carefully to avoid functional abnormalities of the eyelids. Lacerations that involve a significant amount of eyelid tissue but still retain a vascular supply should be repaired (Fig. 64-2). Failure to repair a laceration, or amputating a torn eyelid pedicle rather than a surgically repairing it, can cause moderate to severe exposure-induced corneal ulceration. Accurate two-layer closure of the deep tarsal-to-conjunctival and superficial skin-to-orbicularis muscle layers speeds healing and rapid return to function because it minimizes lid cicatrization and deformity. The eyelid margin should be carefully apposed—a very important step in eyelid repair. Large eyelid lacerations with loss of tissue require general anesthesia and sophisticated blepharoplastic grafting procedures for successful repair.

Lacerations of the margin or body of the nictitating membrane should be carefully repaired to avoid corneal irritation. Removal of the entire nictitating membrane should be performed only if it is severely damaged. The area adjacent to the cornea posterior to the nictitating membrane should always be examined for foreign bodies.

**CORNEAL INJURIES**

**Indication**

Corneal trauma can range from simple ulcers to full-thickness perforations with iris prolapse. Posttraumatic corneal infection and iridocyclitis are always major concerns for even the slightest corneal ulcerations. The type of medical or surgical treatment, or both, is determined by the type and extent of corneal disease and the ocular complications that have occurred. All corneal injuries should be fluorescein stained to detect corneal ulcers.

---

**Figure 64-1.** Orbital drainage is necessary after orbital penetration through the upper lid.

**Figure 64-2.** Severe lid laceration. A, The entire upper eyelid margin of this horse was traumatically lacerated so that it is attached by only a small pedicle at the lateral canthus. B, The laceration was successfully repaired with a two-layer closure.

---

**Abrasions and Ulcers**

**Diagnosis**

Small corneal abrasions are detected through the use of illumination with a light source and fluorescein dye retention. The cornea may be cloudy, the conjunctiva red, and the eye painful. The upper eyelashes may droop. Topically applied antibiotics may help retard bacterial infectious processes but should be used carefully. *Staphylococcus*, *Streptococcus*, and *Pseudomonas* are frequent pathogens of the horse cornea. The use of topically applied corticosteroids in treating corneal ulcers in the horse is contraindicated because the environment of the horse contains many saprophytic fungi, such as *Fusarium* and *Aspergillus*, that are capable of causing devastating fungal keratitis. This fact cannot be overemphasized.

Tear film neutrophils and some bacteria and fungi are associated with highly destructive protease and collagenase
enzymes that can result in rapid corneal stromal melting and perforation in the horse (Fig. 64-3, A). Cytologic examination and microbiologic culturing of deep or rapidly progressing ulcers are imperative.

**Treatment**

Appropriate topically applied antibiotics, such as the triple-antibiotic ophthalmic solutions, and mydriatics or cycloplegics, such as 1% atropine ophthalmic solution, are recommended for equine corneal ulcers. Autologous serum has anticollegenase activity to aid corneal healing, and it should be used topically on ulcers in the horse to minimize stromal melting and speed healing. Systemically administered nonsteroidal anti-inflammatory agents, such as phenylbutazone (2 to 4 mg/kg twice a day, PO) and flunixin meglumine (1 mg/kg twice a day, IM or PO), are also beneficial. Conjunctival grafts provide nutrition, fibroblasts, physical support, and endogenous plasma or serum to the melting ulcer, and they are strongly recommended (see Fig. 64-3, B and C).

A descemetocele can be recognized as a dark clearing at the bottom of a deep ulcer (Fig. 64-4, and see Fig. 64-3, D and E). It does not retain fluorescein dye, whereas the stroma of deep ulcers does retain the dye. Conjunctival or corneal grafts are preferred over nictitans flaps for surgical therapy for a descemetocele. Topically applied antibiotics, serum, and atropine are indicated, as well as systemically administered anti-inflammatory drugs.

**Corneal Lacerations and Perforations**

**Treatment**

Corneal lacerations may perforate a partial thickness or the full thickness of the horse cornea, but they are always accompanied by degrees of iridocyclitis. Medical therapy should be sufficient for superficial, nonperforating lacerations. Topically applied broad-spectrum antibiotics, mydriatics or cycloplegics, and serum are recommended. Topically applied serum reduces enzymatic collagen breakdown of the cornea and prevents rapid dissolution of absorbable corneal sutures. Systemic nonsteroidal anti-inflammatories are strongly indicated.

Small full-thickness corneal perforations may be detected using Seidel's test. Clear aqueous humor leaking from the anterior chamber through a corneal fistula will dilute fluorescein dye placed on the cornea, causing it to be clear or green in Seidel's test (see Fig. 64-3, F). All such full-thickness lesions must be surgically repaired, or infection and/or phthisis bulbi will occur. Deep or irregular corneal partial-thickness lacerations or melting ulcers require surgical support of the cornea and more aggressive therapy for corneal disease and iridocyclitis (Fig. 64-5). Direct corneal suturing, and corneal and conjunctival grafts are indicated to more
rapidly restore corneal integrity (see Chapters 57 and 60). Topically applied antibiotics, mydriatics or cycloplegics, and serum, as well as systemically administered anti-inflammatory drugs, are used until healing is complete.

Full-thickness corneal perforations are usually associated with shallow anterior chambers and iris prolapse (Fig. 64-6). Hyphema and fibrin may be present in some eyes (Fig. 64-7). If the corneal lesion extends to the limbus, the sclera should also be carefully checked for perforation, because a scleral tear can be obscured by conjunctival chemosis and hemorrhage. Failure to detect such a scleral rupture results in chronic hypotony and globe atrophy (phthisis bulbi).\(^1\)\(^3\)

Both small and large corneal perforations should be surgically repaired. Complications include infection, iris prolapse, anterior and posterior synechiae, cataract formation, and persistent iridocyclitis. Both small and large corneal or scleral defects can result in phthisis bulbi if left untreated.\(^1\)\(^3\) Successful surgical repair of the iris prolapse and corneal perforation requires good illumination, good magnification, and proper microsurgical instrumentation. Eyes with an iris prolapse present for over 2 weeks, secondary to infected or sterile melting ulcers, and associated with corneal lacerations greater than 15 mm in length generally have a poor outcome in reference to sight and may result in enucleation as a result of endophthalmitis or phthisis bulbi.\(^7\)
Prognosis

The prognosis of a full-thickness corneal perforation depends on the duration and size of the wound (see Fig. 64-6), the amount of iris and lens involvement, and the presence of infection and hemorrhage.1,3,7 A horse with a traumatic corneal perforation that defies repair and that has extensive extrusion of intraocular contents, severe intraocular hemorrhage, or evidence of bacterial infection should have the affected globe enucleated (see Fig. 64-7). Severe intraocular hemorrhage usually results in phthisis bulbi, because the eye of the horse does not tolerate much damage to its vasculature. Septic intrusion into the globe results in painful endophthalmitis. Such infection can spread to surrounding soft tissues and necessitates enucleation.

CHEMICAL BURNS

Etiology

Chemical burns are among the most urgent of ocular emergencies and may involve the eyelids, conjunctiva, and cornea.8 Insecticide sprays or ointments, antiseptic solutions containing detergents, dermatologic creams containing alcohol, grooming soaps, and other caustic substances can cause blepharospasm, epiphora, and corneal ulceration. The extent of damage and prognosis for recovery after chemical injury of the eye depend on a multiplicity of factors, including the type and amount of the agent involved, its pH, and the duration of contact.8 Alkali injuries are more damaging to the globe than injuries caused by acids. Alkalis are water-soluble substances that release hydroxyl ions and have a basic pH. The higher the pH, the greater the damage to the eye, with the most significant injuries occurring at a pH of 11 or higher.8 Alkalis saponify corneal and conjunctival epithelial cell membranes and intercellular bridges, which facilitates rapid penetration into the deeper corneal stroma. In the corneal stroma, alkalis cause damage and necrosis by binding to mucopolysaccharides and collagen.8 Leukocytes are attracted and release high levels of proteinases.7 Alkali-induced ulcers resemble the collagenase ulcers caused by Pseudomonas bacteria.3,8 Corneal perforation is highly likely in alkali injuries.

Acids dissociate in water to form hydrogen ions. Free hydrogen ions cause cellular necrosis. The intact corneal and conjunctival epithelia offer moderate protection against penetration of dilute or weak acids, allowing little damage unless the pH is 2.5 or lower.8 Acids quickly denature
proteins in the corneal stroma, forming precipitates that retard additional penetration. Acidic chemicals thus generally yield more superficial, sharply demarcated, and self-limiting corneal lesions.8

Treatment
Chemical burns should be quickly lavaged to bring the pH to normal levels with copious quantities of saline or water until the offending substance is removed. This may be the most important determinant for the ultimate prognosis of the insult to the eye. Topically applied antibiotics, atropine, and large amounts of antiproteinases, such as endogenous serum or ethylenediaminetetra-acetic acid (EDTA; 0.2%), are used until healing is complete.3,8 Severe cases may warrant continuous perfusion of medication through a subpalpebral lavage system. The conjunctival fornices should be carefully flushed to remove any sequestered chemical. Systemically administered antibiotics, nonsteroidal anti-inflammatory agents, and analgesics are also beneficial. Topically applied corticosteroids interfere with the corneal healing process and are contraindicated. Topically applied corticosteroids (dexamethasone or prednisolone acetate, four times a day) and systemically administered anti-inflammatory drugs (phenylbutazone, 1 g twice a day, PO) are also needed to suppress inflammation. This author has successfully used tissue plasminogen activator (TPA; Activase, Genentech, South San Francisco, Calif) for a horse suffering from traumatic uveitis when a severe amount of fibrin was present in the anterior chamber. TPA can digest blood clots and should not be used in the presence of hyphema. A dose of 50 to 100 µg of TPA is injected into the affected eye.

THERMAL BURNS
Fire can cause damage to the adnexa, cornea, and conjunctiva in horses. After copious irrigation and débridement, superficial cutaneous injuries are allowed to granulate during the healing process.9 Antibiotic ointments and non-adherent dressings are used for wound coverage and as a prophylaxis for infection. Artificial tear ointments may be needed to lubricate the cornea if lagophthalmos is present. When deep dermal injuries occur in association with severe third-degree burns, the wound should be gently cleaned and carefully débrided. The early application of a meshed or split-thickness skin graft reduces subsequent scarring and ectropion. A tarsorrhaphy should be performed to provide corneal protection and to keep the eyelids tightly against the globe until swelling subsides. The vigorous use of antibiotic ointments is essential in the early phase of wound healing to prevent infection. Cicatricial entropion and ectropion (Fig. 64-8) may occur and may require skin grafting, skin advancement flaps, or other extensive blepharoplasty procedures.

Figure 64-8. Cicatricial ectropion in a horse that escaped a barn fire.
FOREIGN BODIES
Etiology and Diagnosis
The effect of a foreign body on the eye depends on its size, its location, the type of material, and the length of time in the eye. Iron, copper, and vegetative material are poorly tolerated intraocularly. Infectious agents can cause severe damage when associated with foreign material in the eye. Foreign bodies may be found in the eyelids, in conjunctival fornices, behind the nictitating membrane, in the cornea, and intraocularly. Corneal, conjunctival, and eyelid foreign bodies can cause nonhealing superficial corneal ulcers (Fig. 64-9, A and B). Vitreal or retinal foreign bodies are difficult to identify and nearly impossible to remove at the present level of sophistication in equine ophthalmology. Metallic foreign bodies can be confirmed by skull radiography and ocular ultrasonography (see Fig. 64-9, C and D). It is rarely feasible or beneficial to remove a gunshot pellet from within the eye or orbit.

Treatment
Superficial corneal foreign bodies can be quickly removed with topical anesthesia, sensory and motor nerve blocks, and sedation (see Fig. 64-9, A and B). Penetrating or deep foreign bodies may need to be removed under general anesthesia. The corneal puncture wound caused by a foreign body should be treated with topically applied antibiotics. Systemically administered antibiotics, anti-inflammatory agents, and topical mydriatics or cycloplegics are also beneficial. Topically applied corticosteroids are contraindicated in corneal lesions associated with vegetative matter. A foreign body in the anterior chamber or lens may be removed through a limbal incision. If a foreign body is of nonreactive material and if the ocular tissues penetrated do not react to the insult, surgical removal may be contraindicated when the surgical procedure would create more inflammation than the foreign body itself.

ENDOPHTHALMITIS
Etiology and Diagnosis
Severe endophthalmitis can result from septicemia, orbital surgery, intraocular surgery, corneal perforations, ruptured descemetoceles or ulcers, lens capsule rupture, or entrapped vitreal foreign bodies. It may be of a septic or sterile nature. Intraocular infections causing endophthalmitis, whether bacterial or fungal, are devastating in the horse. Culture of aqueous and vitreous aspirates is imperative for the correct diagnosis and should be carried out immediately.

Figure 64-9. A, Small dark corneal foreign body has induced corneal vascularization. B, When the foreign body is removed, a small fluorescein-positive ulcer is present that requires therapy. C, Radiograph showing an orbital foreign body. Gunshot pellets are present near the orbit. D, Ultrasonography was used to locate the intraorbital and intraocular pellets.
Treatment

A dosage of 2 to 5 mg of gentamicin in 0.1 mL of solution is injected intravitreally if gram-negative organisms are isolated; in gram-positive infections, 2.2 µg of intravitreally applied cefazolin is recommended. In fungal endophthalmitis, fluconazole (10 mg/kg of body weight) is administered intravenously or orally. Medical therapy must be aggressive and may require systemic antibiotics and repeated intravitreal antibiotic injections. Vitrectomy should also be considered. Painful blind globes with endophthalmitis should be enucleated.

BLINDNESS
Etiology and Diagnosis

It is critical for the veterinarian to assess whether the horse truly became acutely blind. An ocular examination and a carefully assembled history helps determine this factor. Acute blindness associated with head or ocular trauma may result from glaucoma, cataracts, intraocular hemorrhage, retinal or optic nerve disease, or brain injury.

The optic nerve is contained within a dural sheath that is continuous at the orbital apex with the peristeum of the optic canal. Traumatic optic neuropathy occurs in the optic canal where the dural sheaths and the peristeum are fused. Concussive shock waves focused on the optic canal may result in optic nerve damage because the nerve is fixed and experiences the same force as the surrounding bone. Stretching, shearing, or avulsion of the equine optic nerve or chiasm can result in optic nerve atrophy and blindness from concussive cranial injuries. Fractures of orbital bones, cerebral edema, and vascular infarction in the horse may also play a role in blindness as a result of head trauma.

Chorioretinal degeneration and optic nerve atrophy are also reported secondary to acute blood loss caused by trauma or surgery in the horse. Surgery to eliminate epistaxis induced by guttural pouch mycosis using the ligation technique for the internal and external carotid and the greater palatine arteries can be associated with ischemic optic neuropathy and sudden irreversible blindness in horses.

Treatment

Systemically administered nonsteroidal anti-inflammatory agents and dimethyl sulfoxide may be beneficial in treating or preventing blindness in cases of acute head injury. A thorough ophthalmic and physical examination is necessary to identify the cause of the blindness for specific therapy.

REFERENCES

ANATOMY AND PHYSIOLOGY

Scrotum

The scrotum is a prepubic diverticulum of skin that contains the testes, their associated ducts, and the distal portion of the spermatic cords. It is divided on the midline by the scrotal raphe, which is continuous with the raphae of the prepuce, penis, and perineum. The skin of the scrotum is thin, sparsely covered with fine hair, and contains an unusually high number of sweat glands.

Intimately adherent to the scrotal skin is a layer of connective tissue and involuntary muscle, the tunica dartos. This muscle relaxes with heat and contracts with cold to regulate testicular temperature, thus varying the size of the scrotum. At the median plane, the tunica dartos sends a sagittal septum into the scrotal sac, dividing the scrotum into right and left pouches, each of which contains a testis.

The vascular supply to the scrotum originates from the external pudendal vessels. The nervous supply descends into the scrotum on the outer surface of the tunica vaginalis via the genitofemoral nerve. Lymphatic vessels from the scrotum drain to the superficial inguinal lymph nodes.

Epididymis and Testis

The testes produce spermatozoa and hormones. The hormones govern spermatogenesis, sexual differentiation, secondary sexual characteristics, and libido. The testes are oval and, depending on the age and breed of the horse, weigh between 150 and 300 g each. The left testis is usually larger, suspended more ventrally, and situated further caudally than the right testis. The long axis of the testis is nearly horizontal but raised slightly cranially. The epididymis attaches to the dorsolateral border of the testis and overlaps the lateral surface slightly, forming a testicular bursa between the testis and epididymis (Fig. 65-1). Opposite the attached border is the free border, and opposite the lateral surface is the medial surface. The epididymis is an elaborately coiled tube consisting of three parts: the head (caput), body (corpus), and tail (cauda). The head lies at the cranial pole of the testis, and the body is positioned on the lateral surface of the testis. The tail projects beyond the caudal border of the testis, wraps around to the medial side, and continues proximally as the ductus deferens.

The testis is covered by the tunica albuginea, a tough, inelastic capsule of dense fibrous tissue. Trabeculae and septa of connective tissue from the tunica albuginea penetrate the testis to subdivide the parenchyma into lobules. Each lobule consists of convoluted seminiferous tubules lined by spermatogonia, from which spermatozoa arise, and Sertoli cells (also called sustentacular cells), which supply mechanical and nutritive support for the developing spermatozoa. The primary spermatogonia are attached to the basement membrane of the tubule, and the more mature spermatozoa are pushed toward the lumen. Follicle-stimulating hormone produced by the hypophysis...
stimulates spermatogenesis. The seminiferous tubules make up over 70% of the parenchyma of the testis. The seminiferous tubules are interstitial cells, known as the cells of Leydig, which produce androgens in response to interstitial cell–stimulating hormone (which is similar or identical to luteinizing hormone), produced by the hypophysis. The testis of the stallion produces an unusually high concentration of estrogen in comparison to other domestic species, and the source of this estrogen is the cells of Leydig.

The seminiferous tubules converge to form the tubules of the rete testis, which pierce the tunica albuginea at the dorsocranial border of the testis to become the efferent ductules. The dozen or more efferent ductules unite in the head of the epididymis to form a single coiled tube, over 70 m long, that continues to become the body and tail of the epididymis and ascends with the testicular vessels as the ductus deferens. Spermatozoa mature in the epididymal duct, and the duct’s tortuous course allows the storage of a large number of spermatozoa.

Inguinal Canal
The inguinal canal is an oblique passage in the abdominal wall through which traverse the ductus deferens, nerves, and vessels that enter or exit the scrotum and testis. The internal opening of the inguinal canal, the deep inguinal ring, is a dilatable slit, about 16 cm long in the average-size horse, bordered cranially by the caudal edge of the internal abdominal oblique muscle, ventromedially by the rectus abdominis muscle and prepubic tendon, and caudally by the inguinal ligament. The external opening of the inguinal canal, the superficial inguinal ring, is a 10- to 12-cm-long slit in the external abdominal oblique muscle.

The medial border of the superficial inguinal ring lies directly below the medial border of the deep inguinal ring, making the medial wall of the inguinal canal very short. The superficial inguinal ring is directed cranilaterally, and the deep inguinal ring is directed dorsilaterally, making the lateral angles of the rings widely divergent. The length of the canal in a medium-size horse is about 15 cm when measured along the spermatic cord. The wall of the inguinal canal is lined by peritoneum, which forms the tunica vaginalis.

Tunics
The tunica vaginalis, derived from the abdominal peritoneum, continues through the inguinal canal to line the interior of the scrotum and envelope the testis and its associated ducts and spermatic cord (Fig. 65-2). The tunica vaginalis consists of a visceral tunic (tunica vaginalis propria) and a parietal tunic (tunica vaginalis communis). The visceral tunic adheres firmly to the tunica albuginea and covers the testis and associated ducts, except at the dorsal border of the testis, where vessels and the epididymis enter or leave the testis. The parietal tunic is continuous with the parietal peritoneum of the abdomen at the deep inguinal ring and forms a sac that lines the scrotal cavity. This sac is referred to as the vaginal process or vaginal sac, and its opening at the deep inguinal ring is the vaginal ring. The vaginal ring is found, during examination per rectum in the average-size horse, 10 or 12 cm abaxial to the linea alba and 6 or 8 cm cranial to the iliopectineal eminence.
diverticulum of the peritoneal cavity between the parietal and visceral tunics is the vaginal cavity.1,13 This cavity communicates with the peritoneal cavity and normally contains only a small quantity of serous fluid, which serves as a lubricant to facilitate movement of the testis. The right and left vaginal cavities do not communicate.

Gubernaculum
The gubernaculum testis is a fetal, retroperitoneal, mesenchymal cord that extends between the caudal pole of the fetal testis and the scrotum and guides the fetal testis in its descent from the ventral surface of the kidney to its final position in the scrotum10 (Fig. 65-3). The gubernaculum testis can be divided into three parts: the cranial part, which lies between the testis and the epididymis; the middle part, which lies between the epididymis and the point at which the gubernaculum penetrates the abdominal wall at the inguinal rings; and the caudal or scrotal part, which extends from the abdominal wall at the site of the future inguinal canal to the scrotum. The cranial part becomes the proper ligament of the testis and connects the tail of the epididymis to the testis.3,4,10 The middle part becomes the ligament of the tail of the epididymis (also known as the caudal ligament of the epididymis) and connects the tail of the epididymis to the parietal tunic. The caudal part becomes the scrotal ligament and connects the parietal tunic to the bottom of the scrotum. The scrotal ligament of an abdominally retained testis is sometimes referred to as the inguinal extension of the gubernaculum testis.12 These ligaments may be abnormally long if the testis fails to descend.13 Improper function of the gubernaculum may result in abdominal or inguinal retention of a testis.14,15

Descent of the Testis
The gonads arise retroperitoneally from the gonadal ridges caudal to the kidney and differentiate into testes at 40 days of gestation.16,17 By gestational day 55, the testis is suspended cranially by the cephalic (suspensory) ligament and dorsally by the mesorchium. The interstitial cells begin multiplying at 6 weeks of gestation, causing the testis to hypertrophy until, at 5 months of gestation, the testis is nearly as large as that of a mature stallion and contacts both the kidney and the deep inguinal ring. This phase of testicular hypertrophy corresponds with a period of a high serum concentration of estrogen in the mare.18

The gubernaculum extends from the caudal end of the testis to the inguinal canal and ends in a knoblike expansion of the gubernaculum to form the vaginal process. At about 5 months of gestation, the cephalic ligament atrophies, and the epididymis descends into the vaginal process while the testis remains in the abdomen.16,17

At 8½ months of gestation, the gubernaculum begins to shorten. Simultaneously, the testis regresses in size, mainly because of loss of interstitial cells, until during the last month of gestation, when it becomes one-tenth its former size.16 The epididymis and subperitoneal gubernaculum expand in diameter, thus dilating the vaginal ring and inguinal canal. This, along with an increase in intra-abdominal pressure, allows the testis to pass into the inguinal canal at 270 and 300 days of gestation. The epididymis and subperitoneal gubernaculum prevent the testis from moving directly into the scrotum so that, at birth, most testes lie in the inguinal canal. This extra-abdominal gubernaculum prevents the testis from moving directly into the scrotum so that, at birth, most testes lie in the inguinal canal. This extra-abdominal portion of gubernaculum can be quite large at birth and easily mistaken for a testis. The vaginal rings contract to approximately 1 cm in diameter during the first few weeks of neonatal life and become so fibrous that the testis cannot be forced through from either direction.16

Spermatic Cord
The spermatic cord consists of structures carried ventrally by the testis in its migration through the inguinal canal from the abdomen to the scrotum.1,10 The spermatic cord begins at the deep inguinal ring, where its constituent parts converge. It extends obliquely and ventrally through the inguinal canal, passes beside the penis, and terminates at the dorsal border of the testis.1 The structures that make up the cord are the tunica vaginalis; the vessels, nerves, and lymphatics of the testis; and the ductus deferens.1,10,11 Technically, the cremaster muscle is not included as a component of the cord because it lies external to the parietal tunic.3,15 The neurovascular components of the cord are enclosed in the mesorchium, a fold of serous membrane formed by invagination of the parietal tunic along its caudal wall (Fig. 65-4). The mesorchium extends from the origin of the testicular vessels to the testis. The mesoepididymus is a caudomedially located fold of the parietal tunic containing the ductus deferens and the deferential vessels.1,3,4 The mesoepididymus is continuous with the mesorchium. The mesoepididymus is the thin part of the mesorchium between the mesoepididymus and the parietal tunic.

The ductus deferens is a direct continuation of the epididymal duct.1 It stores spermatozoa, and during ejaculation, it propels spermatozoa from the epididymis to the pelvic urethra.1 The ductus deferens is somewhat convoluted.
near the epididymis but straightens as it continues dor-sally.1,2 At the vaginal ring, it separates from other con-stituents of the spermatic cord and turns caudomedially into the pelvic cavity, where it lies in the genital fold. Dorsal to the bladder, it increases in diameter and forms the ampulla, which in the stallion is 15 to 20 cm long and about 1 to 2 cm in diameter. The ampulla is not nearly as pronounced in geldings. Beyond the ampulla, the ductus deferens narrows and opens with the ducts of the seminal vesicles at the ejaculatory orifices on the colliculus semina lis, a protuberance on the dorsal wall of the urethra, located about 5 cm caudal to the internal urethral orifice. The ductus deferens is supplied by the deferential artery, a branch of the cremaster artery.3

The testicular artery, a branch of the abdominal aorta, descends in the cranial part of the cord.1 As the artery descends in the inguinal canal, it becomes greatly convoluted. At the testis, it continues caudally with the epididymis, turns ventrally around the caudal pole of the testis, and travels cranially on the free border, sending off branches didymis, turns ventrally around the caudal pole of the testis, luted. At the testis, it continues caudally with the epi-

The veins divide and convolute to form the pampiniform plexus, which lies around the coiled testicular artery and forms the bulk of the spermatic cord.1,3,4,7 The veins unite within the abdomen to become the testicular vein. The right testicular vein usually joins the caudal vena cava, and the left testicular vein usually joins the left renal vein.1 The lymphatic vessels of the testis and epididymis ascend directly to the medial iliac and lumbar lymph nodes.1,3,4 A plexus of autonomic and visceral sensory nerves accompany the blood vessels to supply the testis and epididymis.

The cremaster muscle, a slip of the internal abdominal oblique muscle, lies on the caudolateral surface of the parietal tunic and attaches to this tunic at the caudal pole of the testis.1,10 Its blood supply is the cremaster artery.3,4 Contraction of the cremaster muscle retracts the testis.1

**PATHOPHYSIOLOGY**

**Congenital Monorchidism**

Horses possessing one descended testis and one that has failed to descend are sometimes described incorrectly as being monorchids.20 The term monorchid should be reserved to describe the more uncommon situation of complete absence of one testis. Horses in possession of only one testis usually reach this state from failure of a surgeon to remove both testes at the time of castration, but the condition can also occur from unilateral testicular agenesis or when a vascular insult, presumably caused by torsion of the spermatic cord, causes an abdominally located testis to degenerate.21-26

Monorchidism of an apparently congenital nature is usually caused by testicular degeneration rather than by atresia,22 and the vascular insult responsible for the degeneration may occur before or after birth.21,22,27 Torsion of the spermatic cord of the abdominal testis may cause the horse to show moderate to severe signs of abdominal pain,28 but some similarly affected horses do not demonstrate any signs of pain (author’s observation).27

Congenital absence of testicular tissue or absence of testicular tissue caused by testicular degeneration is discovered when, during inguinal or abdominal exploration to locate a cryptorchid testis, the tail of the epididymis is found attached to both the ligament of the tail of the epididymis and the ductus deferens, but the testis is absent.21-26 More rarely, the epididymis or even the ductus deferens may also be missing. Monorchidism can be confirmed with a human chorionic gonadotropin (hCG)-stimulation test, after the contralateral testis is removed and the horse has recovered from surgery, but determining whether monorchidism was caused by degeneration, atresia, or surgical excision of the testis may be difficult.22 The presence of a vaginal process suggests that monorchidism was acquired, and identifying remnants of the cremaster muscle, ductus deferens, and testicular vessels within the inguinal canal suggests that the testis was excised.

**Cryptorchidism**

Cryptorchidism is an anomaly of testicular position and is the most prevalent, nonlethal developmental defect of the horse.16,29,30 Abnormal testicular location occurs when one testis or both testes fail to descend completely from the fetal position in the sublumbar area through the inguinal canal into the scrotum.16 The term cryptorchid refers to the non-descended testis (by extension, a horse with this condition is also termed a cryptorchid), and removal of a cryptorchid testis is sometimes referred to as cryptoorchidectomy. Colloquial terms for the cryptorchid include rig, ridging, or original.31-33 If a testis and its epididymis are both abdom-
inantly retained, the horse is termed a complete abdominal cryptorchid. If the epididymis, but not the testis, has descended through the vaginal ring, the horse is termed a partial or incomplete abdominal cryptorchid.  

An inguinal cryptorchid or "high flanker" is a horse with a testis retained within the inguinal canal.

Cryptorchidism of stallions is of considerable economic significance, because the seminiferous tubules of the cryptorchid testis are rudimentarily developed and incapable of producing sperm.  

Unilateral cryptorchids are usually fertile but have reduced production of sperm,  
and horses affected with bilateral testicular retention are sterile.  

The androgen-producing cells of Leydig of a cryptorchid testis are functional and produce testosterone, although at reduced concentrations, so that the cryptorchid horse exhibits sexual behavior. Exposure of the testis to the high temperature of the abdomen or inguinal canal appears to be responsible for hypoplasia of the seminiferous tubules and results in a small, soft testis. Location of the testis at sites other than the scrotum complicates removal of the testis. Because malfunction of descent may be inherited, cryptorchid horses are generally considered genetically unsound.  

For this reason, registration of cryptorchid stallions is disallowed by some breed associations.  

An epidemiologic survey investigating the prevalence of equine cryptorchidism found that approximately one of six (i.e., about 17%) 2- to 3-year-old colts presented to a veterinary medical teaching hospital was cryptorchid.  

Groups most commonly represented were Percherons, American Saddlebreds, American Quarter Horses, ponies, and cross-bred horses. Thoroughbreds had the lowest prevalence of cryptorchidism.

**Etiology**

Improper function of the gubernaculum has been postulated to cause failure of testicular descent.  

Failure of the subperitoneal portion of the gubernaculum to enlarge may result in failure of the vaginal ring to expand sufficiently to allow the testis to pass. Excessive enlargement of the subperitoneal portion of the gubernaculum, followed by its failure to regress adequately, may also inhibit passage of the testis into the inguinal canal.  

Fetal endocrinologic events that control proper growth of the gubernaculum and regression are obscure, but studies of testicular descent in the pig indicate that the fetal Sertoli cells or primitive germ cells may be responsible for enlargement of the gubernaculum, and that fetal estradiol may be responsible for regression of the gubernaculum.  

The source of fetal estradiol is unknown.  

Fetal testosterone and fetal gonadotropins do not appear to be essential for normal testicular descent.

The tests may fail to descend if it does not regress to a sufficiently small size to traverse the vaginal ring.  

A testicular cyst or teratoma or persistence of the suspensory ligament of the testis during gestation may account for failure of testicular descent.

Although genetic studies of cryptorchid horses indicate that in many instances the condition is hereditary, no definitive studies have supported a plausible genetic mechanism. The effects of maternal environment and mechanical factors (e.g., dystocia) in the etiology of cryptorchidism have not been examined.  

The conflicting observations of numerous studies of genetic transmission of equine cryptorchidism suggest that the mechanism of inheritance is complex and most likely involves several genes. One of the most frequently cited investigations is a thesis published in 1943 on the genetic nature of cryptorchidism of several species of domestic animals. The Technical Development Committee of Great Britain (1954), citing this thesis, concluded that equine cryptorchidism is transmitted by a dominant factor.  

Another German study, however, concluded that equine cryptorchidism is transmitted as an autosomal dominant gene.  

Researchers at Texas A&M University found that 56 of 58 colts sired by a cryptorchid American Quarter Horse stallion had both scrotal testes.  

The other two colts were unavailable for assessment of testicular location. This stallion was unlikely to have carried a dominant autosomal gene for cryptorchidism, unless the gene had low penetrance. If equine cryptorchidism is caused by an autosomal recessive gene, the frequency of the recessive gene in the dams of these 56 colts would have had to have been nearly zero.

Cryptorchidism is often a feature of intersexuality.  

For example, the testes of the male pseudohermaphrodite are often located within the inguinal canals or the abdomen. Cryptorchidism may also be a manifestation of an abnormal karyotype.  

Horses that are cryptorchid because of an aberration of genetic sex, however, are usually easily identified by their intersexual phenotypes.  

The prevalence of horses that are cryptorchid because of intersexuality appears to be quite low; in a study of 5018 cryptorchid horses, only nine were intersexes.

**Incidence**

Retrospective studies of large numbers of cryptorchid horses indicate that failure of right and left testicular descent occurs with nearly equal frequency.  

Right-sided testicular retention predominates in young cryptorchid ponies, but the incidence of right-to-left retention decreases as the ponies age.  

The decrease in incidence of right testicular retention is probably the result of descent of the right testis from an inguinal location.  

A study of 350 cryptorchid horses and another of 205 cryptorchid horses found abdominal testicular retention to be more common than inguinal testicular retention.  

Another study of 500 cryptorchid horses, however, found inguinal cryptorchidism to be more common than abdominal cryptorchidism.

The study of 350 cryptorchid horses found that 75% of left, undescended testes were located within the abdomen, whereas only 42% of right, undescended testes were retained abdominally. The reason for this difference may be that the right testis is smaller than the left during the stage of testicular regression. Consequently, if the gubernaculum fails to expand sufficiently to dilate the vaginal ring, or if the testes incompletely regress in size, the larger
left testis is more likely to be incapable of traversing the vaginal ring. Because this difference in testicular size remains after birth, the smaller right testis is more apt to be inguinally retained. Increase in testicular size with the onset of puberty may cause an inguinally retained testis to descend into the scrotum.44,45

In one study, 14% of cryptorchid horses were bilaterally affected, and most of these (60%) had abdominal testicular retention.46 Another study found a 9% incidence of bilateral testicular retention among cryptorchid horses, but in that study, most bilaterally retained testes (67%) were inguinally located.44 The incidence of cryptorchid horses with one inguinally located testis and one abdominally located testis was quite low in both studies (i.e., when both testes of a horse had failed to descend into the scrotum, the testes were usually either both inguinal or both abdominal).

Inguinal Herniation and Rupture

Inguinal herniation occurs when intestine, usually a portion of the ileum or a loop of the distal portion of jejunum, protrudes through the vaginal ring into the inguinal canal. If the contents extend into the scrotum, the condition is sometimes referred to as scrotal herniation (Fig. 65-5), but the terms are used interchangeably.47,48 Inguinal hernias are sometimes called indirect hernias, a term borrowed from descriptions of the comparable condition in humans.47

A ruptured inguinal hernia occurs when intestine protrudes through the vaginal ring and then passes through a rent in the parietal tunic and scrotal fascia so that it lies subcutaneously in the inguinal or scrotal region (Fig. 65-6). The term inguinal rupture describes a similar condition, which occurs when intestine protrudes through a rent in the peritoneum and transverse fascia adjacent to the vaginal ring, causing intestine to reside subcutaneously beside the vaginal process49 (Fig. 65-7). Inguinal ruptures have been referred to as direct hernias,50 but this term is derived from descriptions of hernias in humans and inaccurately describes the condition in horses.47 In humans, the transverse fascia adjacent to the vaginal ring becomes weakened and protrudes, forming a peritoneum-lined sac. In horses, the integrity of the tissue adjacent to the vaginal ring is disturbed, and the intestine passing through the rent is not surrounded by peritoneum. The purported direct hernias of horses are actually ruptures, not hernias.47,51

Etiology

Inguinal herniation and rupture occur almost exclusively in stallions,48,49,52 but inguinal herniation has been reported in a few geldings,46,53,54 and a mare.55 Geldings seldom develop inguinal herniation, because the vaginal rings decrease in size soon after castration.

Inguinal hernias of foals are congenital, and most are hereditary.6 The left inguinal canal is most often involved.56 Congenital inguinal herniation may be caused by excessive outgrowth of the extra-abdominal part of the gubernaculum, which results in a vaginal process with an unusually wide neck.7,14 Congenital inguinal hernias may occur unilaterally or bilaterally, are usually reducible, cause no strangulation, and spontaneously resolve by the time the foal is 3 to 6 months old.47,54 Longstanding, congenital, inguinal hernias may lead to testicular atrophy.54

Figure 65-5. Inguinal hernia. Intestine protrudes through the vaginal ring into the inguinal canal or scrotum. The intestine lies within the vaginal cavity.

Figure 65-6. Ruptured inguinal hernia. Intestine protrudes through the vaginal ring and passes through a rent in the parietal tunic and scrotal fascia so that it lies subcutaneously in the inguinal or scrotal region.
Inguinal hernias occurring in adult horses are usually acquired and can occur during exercise or copulation, either of which may contribute to herniation by altering the anatomy of the inguinal canal and increasing abdominal pressure. The incidence of acquired inguinal herniation in Standardbreds is reported to be higher than that of the general equine population. Other breeds with anecdotal evidence of increased incidence of inguinal herniation are Tennessee Walking Horses and American Saddlebreds.

An acquired inguinal hernia of an adult horse commonly results in strangulation of small intestine and represents a surgical emergency. Clinical signs are usually referable to obstruction of the small intestine and include recovery of nasogastric reflux after nasogastric intubation and rectally palpable, distended small intestine. Strangulation of herniated intestine is caused by constriction of the intestine by the vaginal ring. An acquired inguinal hernia usually causes obstruction of the vasculature of the spermatic cord, which leads to edema of the external genitalia and testicular degeneration or necrosis.

Abdominal compression during parturition may be responsible for ruptured inguinal herniation in foals. Ruptured inguinal herniation appears to occur much less commonly in adults than in foals. In adults, inguinal rupture is primarily traumatic in origin, but in foals, it occurs much less commonly than does ruptured inguinal herniation. With an inguinal rupture or a ruptured inguinal hernia, the intestine that protrudes through the rent may become strangulated or may adhere to subcutaneous tissue, and the separation of the skin from its blood supply may reduce the viability of the skin.

Torsion of the Spermatic Cord

Torsion of the spermatic cord occurs when the attached testis rotates on its vertical axis. The condition is sometimes improperly referred to as testicular torsion. Torsion of the spermatic cord causes the testicular vessels to twist, producing venous and often arterial obstruction, which leads to testicular congestion and edema in mild cases and complete testicular infarction in severe cases (Fig. 65-8). Clinically significant torsion of the spermatic cord in the horse occurs rarely, and few reports of the condition can be found. This condition is reported to occur most commonly in trotting Standardbreds.

Torsion of the spermatic cord of 360 degrees or more is accompanied by signs of acute pain, which may resemble signs of colic pain, and enlargement of the affected testis and cord. The condition is a surgical emergency that usually requires removal of the affected testis, because the testis is rarely salvageable. Torsion of the spermatic cord of an abdominally located testis may cause the affected horse to show mild signs of colic pain, but acute torsion of the spermatic cord has been recognized during cryptorchidectomy of several apparently normal horses that apparently displayed no signs of colic (author’s observation). Evidently, torsions less than 180 degrees cause no clinical abnormalities and are considered an incidental finding. Evaluation of testicular blood flow of stallions using color Doppler ultrasonography, however, shows that 180-degree torsion of a spermatic cord may cause retrograde blood flow and suggests that torsion of this degree may have a detrimental effect on testicular function, even in the absence of clinical signs of substantial vascular compromise.

Torsion of the spermatic cord of 180 degrees is relatively easy to diagnose because it causes the tail of the epididymis to reside in the cranial portion of the scrotum, rather than in its normal caudolateral position in the scrotum. Torsion of the spermatic cord may be difficult to determine when the spermatic cord is twisted 360 or 720 degrees, because the tail of the epididymis resides in its normal caudolateral position in the scrotum. Torsion of the spermatic cord of 360 degrees or more may be accompanied by so much scrotal, testicular, and epididymal swelling that palpation of the epididymis is not possible.

Torsion of the spermatic cord of the descended testis of horses apparently occurs intravaginally (i.e., within the vaginal process). Torsion may occur because the ligament of the testis is not attached to the scrotum, and the testis may rotate on its axis within the vaginal process. When the epididymis becomes necrotic, the horse may exhibit signs of acute pain, and surgical intervention may be necessary to avoid testicular infarction.
the tail of the epididymis (caudal ligament of the epi-
didymis) or the proper ligament of the testis is abnormally long. The ligaments of the contralateral testis may also be abnormally long, making that spermatic cord also prone to
torsion.64 To prevent torsion of the contralateral spermatic
cord, the contralateral testis can be fixed permanently in
position (orchiopexy) by placing a nonabsorbable suture
through the tunica albuginea and the dartos tissue at the
cranial and caudal poles of the testis.

The spermatic cord of an abdominal testis may be more
apt to develop torsion than the spermatic cord of a
descended testis, because the proper ligament of the testis
and sometimes the ligament of the tail of the epididymis of
an abdominal testis are abnormally long.65,67,69 None of 350
cryptorchid horses in one study, however, developed torsion
of the spermatic cord.46

Hydrocele (Vaginocele) and Hematocele
A hydrocele, or vaginocele, is an abnormal collection of
serous fluid between the visceral and parietal layers of the
tunica vaginalis.66,67 Hydroceles form when fluid normally
secreted by the vaginal tunic is produced at a rate greater
than that at which it can be absorbed by the lymphatic
vessels and veins of the spermatic cord.68 The cause of the
discrepancy between the rate of production and the rate of
resorption of the fluid is usually idiopathic.67 Hydroceles
may accompany testicular neoplasia or orchitis, and because
the vaginal and peritoneal cavities communicate, some
hydroceles could be caused when fluid present in excess in
the abdominal cavity enters the vaginal cavity.69 Migration
of parasites through the vaginal cavity, 180-degree torsion of
the spermatic cord, trauma, and a hot climate in conjunc-
tion with lack of exercise have been implicated as causes of
hydroceles.67,70 Hydroceles may develop acutely or insidi-
ously. They are generally considered to cause temperature-
duced dysfunction of spermatogenesis by insulating the
testis and epididymis, but one investigation found they
cause no important effect on semen quality.67 The size of a
hydrocele may reduce temporarily with exercise, and some hydroceles may spontaneously resolve when the affected horses are moved to a cooler environ-
ment.67,69 Fluid usually re-forms quickly after aspiration.

A horse with a hematocele may be treated successfully by
aspiration of blood from the vaginal cavity followed by
lavage of the cavity with a balanced electrolyte solution,
provoked that the tunica albuginea is not ruptured.73 This
treatment may minimize the insulating effect of blood and
reduce the formation of adhesions between the visceral
and parietal layers of the tunica vaginalis. If torn, the tunica
albuginea should be sutured, or the testis should be
removed.

Varicocele
A varicocele is an abnormally distended and tortuous
pampiniform plexus.66,74 Valvular incompetence of the
testicular vein, where it empties into the vena cava or renal
vein, may increase hydrostatic pressure in the pampiniform
plexus by causing reflux of caval or renal blood into the
testicular vein.74 Varicoceles disturb countercurrent exchange
of heat from the arterial to the venous blood, causing
temperature-induced dysfunction of spermatogenesis.66,74
Although varicoceles are known to cause infertility in men
and rams, their effect on fertility of horses has not been
evaluated, perhaps because varicoceles of stallions are so
infrequently encountered. Unilateral varicoceles have been
noted in some stallions with normal ejaculates.75 Varicoceles
of stallions usually occur unilaterally and, when palpated,
do not cause the horse to display signs of pain. The affected
spermatic cord has the texture of a "bag of worms," and the
neck of the scrotum on the affected side may be wider than
usual.

Treatment of stallions with varicoceles is removal of the
affected cord and testis, but treatment is not necessary if the
varicocele does not affect seminal quality. Humans affected
with varicocele have been treated by ligation of the venous
loops of the pampiniform plexus.76

Testicular Neoplasia
The classification of testicular neoplasms of horses is far less
extensive than that of humans. Primary testicular tumors
are usually divided into germinal and nongerminial types.
Germinal neoplasms arise from germ cells of the spermatic
epithelium, and nongerminial neoplasms arise from testic-
ular stromal cells. Reported germinal testicular tumors of the
horse include the seminoma, teratoma, teratocarcinoma, and embryonic carcinoma. Nongerminal testicular tumors of the horse are the Sertoli cell and Leydig cell tumors. Secondary tumors (i.e., tumors that are the result of metastases) of the equine testis are extremely rare.

The prevalence of primary testicular neoplasia in horses is unknown but is probably low, perhaps because most stallions are castrated while young, before neoplasia has had an opportunity to develop, and perhaps because testes removed from apparently normal stallions are seldom examined closely for the presence of neoplasia. Consequently, the few acknowledged characteristics of testicular neoplasms of horses have been established by collecting information gathered from a small number of case reports. Characteristics of equine testicular neoplasms, such as hormonal effects, tendency toward malignancy, and relationship to cryptorchidism, have been inferred from characteristics of testicular neoplasms of other species more commonly affected, such as humans and dogs. Characteristics of testicular neoplasms differ among species, so extrapolating characteristics of testicular neoplasms of other species to horses may result in mistaken assumptions.

Testicular enlargement is the primary presenting sign of testicular neoplasia when the neoplastic testis is located scrotally. Usually, the enlargement is of an insidious nature. Signs of tenderness during palpation are uncommon but may be a feature of the neoplastic testis. The surface of the neoplastic testis may be characterized by multiple, irregular bumps, and the consistency of the testis may be firmer than normal. Horses with neoplastic abdominal testes may be presented for examination because of intermittent signs of colic. Metastases may cause weight loss or dyspnea. Identifying a tumor is difficult without histologic examination of either the entire testis or tissue obtained by biopsy. Their biologic behavior in horses is unknown because of the small number of reports, but in dogs and people, these tumors often cause hyperestrogenism and feminization.

Malignant Sertoli cell tumors of dogs are rare, but of the few Sertoli cell tumors of horses that have been reported, several were malignant. A malignant Sertoli cell tumor that had metastasized to many organs was found in a descended testis of a horse, and a malignant Sertoli cell tumor that also had metastasized to many organs was found in an abdominal testis of another horse believed previously to be a gelding. Whether cryptorchidism is a predisposing factor to development of the Sertoli cell tumor cannot be determined from the few reports. The sectional surface of a Sertoli cell tumor is firm, white or tan, and homogeneous.

Seminoma
Seminomas arise from the germinal cells of the seminiferous tubules and are the most common testicular tumors of horses. These tumors probably do not produce hormones. As in other species, seminomas of the horse seem to appear with greater frequency in cryptorchid testes and are most commonly found in old horses. Although most equine seminomas behave benignly, they have a higher incidence of malignancy than do some of the other types of testicular neoplasms, and they metastasize more frequently. The relative risk of a seminoma in a human becoming malignant is highest if the testis is abdominal. But no such correlation has been made between the location of a seminoma in the horse and malignancy. All seminomas of horses should be considered potentially malignant, because clear histologic differentiation between benign and malignant seminomas is almost impossible. Abdominal invasion should be suspected if an enlarged spermatic cord can be palpated externally. Thoracic metastasis has been reported. The sectional surface of a seminoma is lobulated, homogeneous, and white or grayish white (Fig. 65-9). The tumor is soft to moderately firm, and when squeezed, the surface may exude a milky fluid.

Sertoli Cell Tumor
The Sertoli cell or sustentacular cell tumor of the horse arises from the nongerminal cells of the seminiferous tubules. Sertoli cell tumors of horses are less frequently encountered than are other types of testicular tumors. Their biologic behavior in horses is unknown because of the small number of reports, but in dogs and people, these tumors often cause hyperestrogenism and feminization.

Leydig Cell Tumor
The interstitial or Leydig cell tumor is an infrequently reported equine testicular tumor. Although these tumors arise from the androgen-producing cells of the testis, evidence of production of androgenic hormones by these tumors is lacking in horses and other animals. Because the Leydig cells of the testes of horses secrete a large amount of estrogen, in addition to androgenic hormones, the hormonal effect of Leydig cell tumors in the horse could vary. Cryptorchidism may be associated with this neoplasm on the basis of the observation that, in a study of nine
stallions affected unilaterally or bilaterally with Leydig cell tumor, the tumors in all but one horse were found in one or both undescended testes. Most Leydig cell tumors of horses are benign, and metastasis is rare. The sectional surface of the tumor is yellow to brown, which may help grossly to differentiate this tumor from other types of testicular tumors. The demarcation between the tumor and adjacent normal parenchyma is poor.

Teratoma
Teratomas are tumors of multiple tissues whose embryologic origin is different from that of the tissue in which they arise, and evidence indicates that they develop from pluripotential tumor cells capable of giving rise to any type of tissue found in the body. Most teratomas occur in the gonads. Histologic examination of equine testicular teratomas shows that they are benign, slow growing, and composed of mixed, well-differentiated tissues. Derivatives from all three germinal layers, such as bone, cartilage, brain, and respiratory and glandular epithelium, may be present within the testis. Teratomas that consist primarily of cysts lined by squamous epithelium and contain hair have incorrectly been referred to as dermoids or dermoid cysts. The term dermoid, however, should not be used when referring to a teratoma, because unlike dermoids, teratomas display progressive growth.

The teratoma is the second most common form of equine testicular neoplasia. It is found in both descended and cryptorchid testes, but some investigators believe it occurs more frequently in the latter. Others dispute this claim, stating the opposite. Failure of descent of a testis, rather than being a predisposing factor in the formation of a teratoma, may more probably be a result of the teratoma itself.

Teratocarcinoma and Embryonal Carcinoma
Teratocarcinomas are similar to teratomas but contain undifferentiated embryonic tissue interspersed among the disarranged mix of differentiated tissues. Embryonal carcinomas resemble teratocarcinomas but are composed entirely of undifferentiated embryonic tissue. The undifferentiated embryonic tissue is responsible for the malignant properties of teratocarcinomas and embryonal carcinomas. Teratocarcinomas and embryonal carcinomas of the horse are evidently quite rare but appear to be rapidly fatal.

Intersex
Because male and female reproductive organs arise from the same embryonic structures, errors of development may result in a horse that possesses sexual structures common to both sexes. An individual whose sexual identity is confused because of congenital anatomic abnormalities of the genital organs is called an intersex. An animal's sexual identity can be defined according to its genetic makeup, the type of its gonads, or the morphology of its accessory genitals. A normal animal is the same sex in all three categories, but the intersex differs in one of the categories.

Intersexes are divided into three main classes: “true” hermaphrodites, female pseudohermaphrodites, and male pseudohermaphrodites. Hermaphrodites are usually defined on the basis of gonadal sex, with true hermaphrodites having both testicular and ovarian tissue. Pseudohermaphrodites have gonads of only one sex and are classified as male or female, depending on whether the gonads are testes or ovaries.

The true hermaphrodite is much rarer than the pseudohermaphrodite. One gonad of a hermaphrodite may be a testis and the other an ovary, or one or both gonads may consist of both ovarian and testicular tissue (i.e., ovotestes). The hermaphrodite's external as well as internal genitalia usually represent both sexes, but its external genitalia may tend toward either the male or female. Some cases of equine hermaphroditism have been attributed to chimerism resulting from double fertilization or fusion of blastocysts, but other equine hermaphrodites are one genetic sex.

Gonads of the pseudohermaphrodite are of one sex, but the external genitalia resemble those of the opposite sex. The male pseudohermaphrodite is by far the most common intersex of horses and typically has hypoplastic testes within the abdomen or inguinal canal and a penis-like structure, which often resembles a clitoris, emerging from a rudimentary prepuce. The rudimentary "penis" and prepuce are positioned anywhere on the midline from the perineum to a scrotal or abdominal location. Although the phenotypic appearance of a male pseudohermaphrodite is often that of a female, sexual behavior is
that of a male. Most equine male pseudohermaphrodites appear to be masculinized, genetic females (64, XX).

The contradiction between gonadal and genetic sex has not been fully explained.

**DIAGNOSTIC PROCEDURES**

**History and Physical Examination**

History pertaining to problems of the testes and related structures may include such information as infertility, history of unilateral or bilateral testicular retention, enlargement in the inguinal or scrotal areas, testicular pain, and changes in testicular size. Knowledge of events surrounding the onset of testicular pain or increase in testicular size, such as occurrence after exercise or copulation, is sometimes helpful in making a diagnosis. Other considerations include previous urogenital surgery, illnesses, and drug therapy.

Physical examination of the testes and associated structures should include inspection and palpation. Notice should be given to the size, shape, texture, and temperature of the testes, and the horse should be observed for evidence of pain when the testes are palpated. Right and left testes should be compared. The scrotum of a normal stallion usually appears asymmetric, because the left testis has a longer spermatic cord and is, therefore, often more pendulous than the right. With cryptorchidism, the scrotum on the involved side is poorly developed. Scrotal scars should be noted, bearing in mind that a scrotal scar may mean only that an orchidectomy was attempted, not that it was accomplished. Occasionally, scrotal edema may be noted. This does not usually imply disease related to the genitalia but is more likely a consequence of general retention of fluid associated with disease of other systems.

The testes should feel smooth and elastic. Irregularities in size and texture may indicate orchitis, torsion of the spermatic cord, thrombosis of the testicular artery, inguinal herniation, or neoplasia. Often, a neoplastic testis is insensitive to digital compression that would cause a normal horse to show signs of pain. Insidious increase in testicular size is suggestive of neoplasia, whereas acute increase in size may suggest torsion of the spermatic cord, inguinal herniation or rupture, or orchitis. As a testicular neoplasm grows, it may seem to replace the entire organ. The neoplastic testis characteristically feels heavier than the normal testis. Because neoplasia may be associated with inguinal or pelvic lymphadenopathy, palpation per rectum of internal lymph nodes should, if possible, accompany examination for testicular enlargement.

The testes of the prepubescent stallion are often quite small, retractile, and therefore often difficult to palpate. Before declaring the stallion a cryptorchid, a tranquilizer or sedative should be administered to relax the cremaster and thus facilitate palpation. The medial crus of the inguinal canal can be palpated if the palm of the hand is turned toward the abdomen. If the palm is turned toward the thigh, the fingers may pass into the inguinal canal without encountering the ring, because the lateral border of the ring is not as readily palpated. Because the average-size stallion's canal is about 15 cm in depth, only the most ventral part of the inguinal canal can be palpated. An inguinal testis lies with its long axis oriented vertically and is preceded in its descent by the tail of the epididymis.

A partial abdominal cryptorchid can be easily mistaken for an inguinal cryptorchid if the epididymis within an everted vaginal process is, by chance, palpated and mistakenly identified as a small testis. The vaginal rings can be palpated only by examination per rectum.

The epididymis, located on the dorsolateral surface of the descended testis, should be easily identifiable. The tail of the epididymis should be easily palpated on the caudal pole of the testis. If the tail of the epididymis is located cranially in the scrotum, the spermatic cord has rotated 180 degrees. Torsions of 180 degrees or less probably cause no clinical problems. When palpat ing the scrotum of a foal to ascertain if testicular descent is complete, the epididymis should be identified so that the remnant of the gubernaculum is not mistaken for a descended testis.

A bulge in the spermatic cord or scrotum may suggest the presence of an inguinal hernia, hydrocele, or hematocoele. Because the intestinal contents of most acquired inguinal hernias are strangulated, palpation of the scrotum and examination of the vaginal rings per rectum should be part of the physical examination of every adult stallion with signs of intestinal obstruction. Unapparent, congenital inguinal hernias may become apparent after castration. Examining the inguinal area of foals before castration for the presence of a congenital inguinal hernia is especially important to avoid evisceration. If a scrotal hernia is present, palpation may elicit a sensation of crepitis. Occasionally, peristalsis may be noted by movement of the skin overlying the bulge.

A ruptured inguinal hernia or an inguinal rupture should be suspected if the skin over the inguinal or scrotal swelling is cold, edematous, or macerated. A strangulated inguinal hernia or rupture should be suspected when a stallion develops signs of colic after copulation or exercise, especially if a testis and its spermatic cord are swollen and tender. A varicocele should be suspected if the spermatic cord appears larger than normal and has the texture of a “bag of worms.” A hydrocele should be suspected if the scrotum appears to be smooth, nontender, and fluid filled, and the testis is smaller than normal. The presence of a fluid-filled, nontender scrotum after castration is also indicative of a hydrocele.

**Examination per Rectum**

Examination per rectum of the vaginal rings and structures that traverse them may be helpful in the diagnosis and evaluation of some genital abnormalities, such as cryptorchidism, inguinal or scrotal herniation, scirrhous cord, and testicular neoplasia. The vaginal rings and associated structures are located about 6 or 8 cm cranial to the iliopectineal eminence and 10 to 12 cm abaxial to the linea alba in the average-size horse. The vaginal ring is palpable in geldings as a slight depression, but in stallions it is large enough to insert a finger.

The risk of rectal injury should be weighed against the value of the diagnostic information to be gained before performing an examination per rectum. For example, examination per rectum is probably not necessary before removing a cryptorchid testis by an inguinal approach, provided that the owner is confident that orchidectomy has not been attempted previously. If, during surgery, the testis is not encountered in the inguinal canal, it can usually be
extracted from the abdomen through the vaginal ring or through a parainguinal incision. Even though mares are more commonly subjected to examination per rectum, the incidence of rectal injury in geldings and stallions is higher, perhaps because males are less accustomed to the procedure and resist it more forcibly.\(^2\) Most cryptorchid stallions presented for examination are young, and the small size and fractious nature of young horses predispose them to rectal injury during examination per rectum.

To palpate the vaginal rings, the examiner introduces a hand into the rectum until the lateral aspect of the wrist rests on the pubic brim at the pelvic symphysis.\(^1\) The examiner may find it advantageous to palpate the right vaginal ring with the left hand and the left vaginal ring with the right hand. The fingertips are flexed and pressed against the lateral aspect of the abdominal wall, and fingers are extended in a downward and forward direction against the abdominal wall until a finger enters the vaginal ring. If the search is made with a backward flexing motion of the finger, the medial border of the deep inguinal ring tends to close, causing the finger to slide over the vaginal ring. When the vaginal ring is located, the components of the spermatic cord can be felt as a cordlike structure entering the canal. The ductus deferens is more readily palpated at the ring than are the testicular vessels,\(^4\) and it can be palpated on the caudomedial aspect of the ring, if the testis or epididymis has descended.\(^2\)

The vaginal rings should always be examined for evidence of intestinal incarceration when examining a colicky stallion. Palpating distended loops of intestine and a loop descending through the vaginal ring indicates that intestine has become inguinally incarcerated. Traction on the loop usually causes a painful reaction from the horse. For horses with septic funiculitis, thickening of the spermatic cord at the vaginal ring is evidence of ascension of infection into the abdominal cavity. For horses with testicular neoplasia, thickening of the spermatic cord at the vaginal ring suggests that the neoplasm has metastasized. The lymph nodes surrounding the terminal portion of the aorta and its branches should also be palpated for evidence of metastasis.

For a horse with an unknown history of castration that displays masculine behavior, or for a stallion known to be cryptorchid, examination per rectum may be useful in determining whether a testis has traversed the vaginal ring.\(^10\) Determining the location of a retained testis prior to orchidectomy is especially important if a flank or paramedian approach is to be used, because an inguinally retained testis is difficult to remove using any approach other than the inguinal one. Palpating an abdominal testis per rectum is difficult, because the testis is small and flaccid, and because the proper ligament of the testis is usually elongated, allowing the testis a wide range of movement. Palpation of an abdominal testis per rectum by an inexperienced examiner should be regarded as a fortuitous occurrence, and failure to palpate an abdominal testis should not be relied on diagnostically. The vaginal ring cannot be palpated in horses with complete abdominal testicular retention, but palpation of the vaginal ring is evidence that the testis or at least its epididymis has descended through the ring into the inguinal canal. Unfortunately, a partial abdominal cryptorchid cannot be distinguished from a horse whose testes have descended through the vaginal ring by examining the vaginal rings per rectum.

**Testicular Biopsy**

Testicular biopsy is indicated when less invasive diagnostic methods have failed to provide an etiologic or pathologic diagnosis of testicular disease, and when a diagnosis is essential to determine treatment and prognosis.\(^1\) An obviously neoplastic testis should be removed rather than biopsied, because biopsy may disseminate neoplastic cells. Testicular biopsy has been used to a limited extent in the horse, perhaps because of fear of the complications reported after incisional (especially) or needle biopsy of the testes in other species.\(^1,2,11\) Because horses are usually able to maintain breeding soundness after removal of one testis, obviously diseased testes have often been removed rather than biopsied, even though the testicular disease has not been definitively identified.

Biopsy provides the only method for directly assessing stages of spermatogenesis and rates of sperm production and for determining the identity of space-occupying lesions.\(^11\) Biopsy may be helpful in differentiating among causes of testicular enlargement, such as septic orchitis, neoplasia, or trauma. Despite complications reported to occur in other species, aspiration and needle biopsies have been performed successfully in a small number of horses.\(^12,14,15\)

**Aspiration Biopsy**

Aspiration biopsy presents little risk to the horse because decreased spermatogenesis is not a likely complication.\(^11\) Although an aspiration biopsy is less damaging to the testis than a needle biopsy, an aspiration biopsy usually does not offer useful information about spermatogenesis.\(^11\) Its main use is to help determine the cause of testicular enlargement. Aspiration biopsy can be performed by inserting a 23- or 25-gauge needle into the testicular parenchyma.\(^11\) Local anesthesia of scrotal skin is unnecessary. A 12-mL syringe is attached to the needle, and the plunger is withdrawn. The needle is retracted without exiting the parenchyma and is reinserted into several areas. The plunger is released, and the needle is removed from the testis. Although hemorrhage after biopsy is uncommon, digital pressure maintained over the puncture site for several minutes ensures hemostasis. Aspirated material is expelled onto a glass slide, smeared, dried, and stained. Aspirated material should be smeared gently, because cells collected from the testis by aspiration are extremely fragile. The slides should be examined by an experienced cytologist, because normally developing spermatocytes have cytologic characteristics that could lead to a mistaken diagnosis of malignancy.

**Needle Biopsy**

The needle biopsy provides the most useful information about spermatogenesis, and the technique is unlikely to have deleterious effects on the testis.\(^11,12,14\) Needle biopsy of a testis can be performed using a 12- or 14-gauge Vim-Silverman needle\(^12\) or a 12- or 14-gauge automated biopsy
needle (Biopty Biopsy Instrument, CR Bard, Inc, Covington, Ga). Biopsy can be performed with the horse standing and sedated. The scrotum is prepared as if for aseptic surgery, and a small volume of local anesthetic solution is injected subcutaneously at the proposed site of biopsy using a 25-gauge needle. The site of biopsy should be the craniolateral quarter of the testis, away from the head of the epididymis, where the vasculature is the least prominent, unless there is a particular area of interest. The biopsy needle can be guided ultrasonographically to sample a discrete lesion. The testis is held tightly against the scrotal skin, and a small stab incision is created on the lateral surface of the scrotum, down to and through the parietal tunic. The Vim-Silverman needle or automated biopsy needle is inserted through the visceral tunic and tunica albuginea into the testicular parenchyma. Two or three samples are collected through the same skin incision but at slightly different angles. Pressure is maintained over the incision for several minutes, and the cutaneous incision is closed with a single suture. Samples are fixed in Bouin’s solution for 6 to 12 hours, washed, and stored for about 12 hours in 70% ethanol. They are then shipped to a laboratory in 50% ethanol.

Complications associated with needle biopsy of the testis in other species include transient scrotal edema; intratesticular hemorrhage resulting in pressure necrosis; immune reaction to spermatozoa caused by disruption of the blood–testis barrier; dissemination of neoplastic cells if a tumor is biopsied; formation a hematoma between the testis and the parietal tunic or between the parietal tunic and scrotum, which can result in insulation-induced damage to the seminiferous epithelium; and transient decrease in semen quality. Formation of antisperm antibodies and decrease in semen quality reported to occur in other species after testicular needle biopsy have not been reported to occur in the horse.

Hormonal Assays

Occasionally, physical examination is inadequate to determine whether a horse possesses a retained testis, in which case a hormonal assay may be necessary to distinguish between psychic and hormonal causes of persistent masculine behavior. Concentration of testosterone in the plasma or serum can be used to distinguish between geldings and horses with extrascrotal testicular tissue. Stallions with descended testes (sometimes referred to as “entire stallions”) and cryptorchid stallions have significantly higher concentrations of androgens and estrogens in the serum or plasma than do geldings.

In several studies, basal concentration of testosterone in castrated horses was generally less than 40 pg/mL of serum, and that of entire stallions was greater than 100 pg/mL. The concentration of testosterone of entire stallions was often 1000 to 2000 pg/mL, although the concentration during winter was often as low as 200 pg/mL. In one study, geldings were found to have a testosterone concentration in serum of less than 240 pg/mL, and horses with testicular tissue had a concentration of greater than 440 pg/mL. Another investigation found the concentration of testosterone in the serum of stallions to be dependent on the age of the horse and the season, with the concentration being lowest in horses younger than 3 years and during the winter.

Some investigators noted that cryptorchid stallions generally had a slightly lower concentration of testosterone than did entire stallions. In contrast, other investigators observed that mature, bilateral, cryptorchid stallions and hemi-castrated stallions (i.e., unilateral cryptorchid horses whose scrotal testis had been removed) had a similar or higher concentration of testosterone in the serum than did entire stallions. These authors suggested that retained abdominal testes may produce as much or more testosterone than do scrotal testes.

Wide variations in basal concentration of testosterone occasionally lead to confusion. Because the concentration of testosterone in some entire stallions is exceptionally low and that in some geldings is exceptionally high, values may overlap, causing erroneous conclusions to be drawn as to whether a horse possesses testicular tissue. One investigator reported 14% error using basal concentration of testosterone to diagnose retained testes.

![Figure 65-11](image_url)
concentration of testosterone to differentiate geldings from horses with testicular tissue. These wide variations in concentration of testosterone were not observed in another study, which found basal concentrations of testosterone to be accurate in predicting the presence of testicular tissue. That study found an error of only 5%.

A rise in the concentration of testosterone in response to stimulation by administration of hCG increases the accuracy of detecting cryptorchidism. Investigators reported increased concentration of testosterone in cryptorchid stallions at any time between 30 and 120 minutes after intravenous administration of 6000 or 12,000 units of hCG. Horses were classified as cryptorchid if the concentration of testosterone both before and after administration of hCG was greater than 100 pg/mL, or as geldings if the concentration in both samples was less than 40 pg/mL. The hCG-stimulation test was 94.6% accurate in predicting the presence of testicular tissue. Response to hCG was poor in horses less than 18 months old and during the winter. Other investigators found that response of bilateral cryptorchid stallions and semi-castrates to hCG was minimal, but that best results were achieved if poststimulation samples were obtained at 24 hours rather than at 1 hour. Other investigators found that administration of hCG to entire stallions induced an increase in concentration of testosterone that lasted about 10 days, and they suggested that for detection of a retained testis a poststimulation sample should be taken at 2 to 3 days.

In one study, quantification of total, free (i.e., unconjugated) estrogen alone was superior to quantification of total androgens, with or without hCG stimulation, for detecting retained testicular tissue. Although other investigators were unable to confirm superiority of free estrogens for detecting testicular tissue, they found a high correlation between the presence of testicular tissue and the concentration of conjugated estrogen (e.g., estrone sulfate) if cryptorchid horses younger than 3 years and cryptorchid donkeys of any age were excluded from the study. The investigators found that young cryptorchid horses and cryptorchid donkeys did not consistently produce enough conjugated estrogens to yield reliable results. Quantification of conjugated estrogen was 96% accurate when these animals were excluded from the study. Although cryptorchid horses produced less estrogen than did entire stallions, the lower threshold of conjugated estrogen for a cryptorchid horse was higher than that of testosterone. Horses with a concentration of estrone sulfate less than 50 pg/mL in plasma or serum were determined to be geldings. A concentration in excess of 400 pg/mL indicated cryptorchidism. Another investigation also revealed a high correlation between the concentration of conjugated estrogens and the presence of testicular tissue in horses older than 3 years. In that investigation, geldings had a concentration of estrone sulfate less than 120 pg/mL, and cryptorchid stallions had a concentration greater than 1000 pg/mL.

Knowing the laboratory's standards for normal hormonal concentrations of geldings and horses with testicular tissue is important when evaluating results of hormonal assays. Comparing test results with values from a known gelding may be necessary if the laboratory cannot furnish standards. False-positive results from hormonal assays to determine the presence of testicular tissue have not been reported. The clinician can be confident that a horse has testicular tissue if the result of a hormonal assay indicates that testicular tissue is present.

Other Diagnostic Tests

Ultrasoundographic examination may delineate abnormalities within the testes and associated structures or assist in determining the location of a cryptorchid testis. To ultrasoundographically image an inguinal testis, a 5-MHz, transrectal transducer is placed longitudinally over the superficial inguinal ring. To image an abdominal testis, the transducer is inserted rectally, cranial to the pelvic brim, and the abdomen is scanned in a to-and-fro pattern as the transducer is advanced cranially. Inguinal ultrasonography is ineffective in locating an abdominal testis, and furthermore, abdominal ultrasonography is ineffective in locating an inguinal testis. The echotexture of the cryptorchid testis is less dense than that of a normal descended testis.

Serum concentrations of biochemical markers, such as α-fetoprotein and hCG, are measurable in minute quantities using radioimmunoassay and have been used to monitor the response of humans to treatment for testicular neoplasia. Apparently, no such markers have been used to detect testicular neoplasia of horses or to monitor for the presence of metastatic neoplasms after a neoplastic testis has been removed.

Cytologic examination of peritoneal fluid may be valuable in diagnosing certain diseases of the testes and associated structures, because changes in the fluid within the vaginal cavity may be reflected in the peritoneal fluid. Semen evaluation may be valuable in diagnosing orchitis, epididymitis, or seminal vesiculitis. Thermographic examination of the scrotum may detect a variation in temperature between the testes. A horse with morphologic abnormalities suggestive of intersexuality, such as cryptorchidism accompanied by ambiguous genitalia, can be karyotyped to determine its genetic sexual identity.

SURGICAL PROCEDURES

Castration

Indications

Synonyms for castration include orchidectomy, emasculation, gelding, and cutting. Castration is one of the most common equine surgical procedures and is usually performed to sterilize horses unsuitable for the genetic pool and to eliminate masculine behavior. By removing the primary source of androgens, castration renders the horse more docile and manageable.

Although stallions can be safely castrated at any age, managerial convenience usually governs the age at which a horse is castrated. Typically, a horse is castrated simply because facilities are insufficient to safely contain a stallion. Most horses are castrated when they are 1 to 2 years old, when masculine behavior becomes intolerable to the owner. Sometimes castration is delayed until a masculine feature, such as a crest on the neck, has developed or until it becomes apparent that the horse is unsuitable for breeding.
Castration may be performed to alter conformation. Bulls castrated prior to puberty grow to a greater height because castration delays closure of the growth plates of their long bones, and the same may be true of stallions castrated before puberty. Orchitis, epididymitis, testicular neoplasia, hydrocele, varicocele, testicular damage caused by trauma, torsion of the spermatic cord, or inguinal herniation may necessitate unilateral or sometimes bilateral orchidectomy. Impotent or infertile breeding stallions may be salvaged for other uses by castration.

Preoperative Considerations
A general physical examination of the horse should precede castration, and the scrotum, especially that of very young horses, should be inspected for inguinal herniation and for the presence of both testes. Discovery of inguinal herniation or cryptorchidism may affect the choice of anesthesia and the surgical approach. Preoperative sedation of a fractious horse usually permits safe palpation of the scrotal and inguinal areas and occasionally facilitates palpation of an inguinal testis by causing the cremaster muscles to relax.

Standing Castration

CASE SELECTION
Castration performed with the horse standing can be difficult and dangerous to the surgeon if candidates for the procedure are not selected prudently. Standing castration of horses with poorly developed testes and of ponies is mechanically difficult. Donkeys and mules can be dangerous to castrate while they are standing because of their athletic agility. Stallions that elicit a hostile or evasive response to genital palpation may best be castrated while they are anesthetized. Docile stallions with well-developed testes whose genitalia can be palpated without being sedated are usually the safest candidates for standing castration.

PREPARATION OF THE HORSE
Sedating the horse to be castrated while standing is optional but advisable. Drugs commonly used, either alone or in combination, are xylazine HCl, detomidine, pentazocine, and butorphanol tarrate. Acetylpromazine, although commonly administered to tranquilize stallions before castration, can result, on rare occasion, in priapism or penile paralysis, and so its use in stallions should be avoided.

The scrotum must be anesthetized on each side of the scrotal raphe from the cranial to the caudal pole of the testis along the proposed lines of incision. The spermatic cords can be anesthetized by injecting local anesthetic solution, usually 15 to 30 mL, through a 22- to 20-gauge needle directly into each cord. This anesthetic technique ensures good anesthesia of the cord but occasionally causes a hematoma that interferes with application of the emasculator. Alternatively, about 25 mL of local anesthetic solution (without epinephrine) can be injected directly into the parenchyma of each testis through an 18-gauge, 1/2-inch needle. The anesthetic solution diffuses proximally into each spermatic cord. The horse’s tail should be wrapped to prevent it from contaminating the surgical field, and the scrotum should be scrubbed before and after administering the local anesthetic solution.

RESTRRAINT
The horse should be restrained by a competent handler, and to ensure adequate immobilization, application of a lip twitch may be necessary. The standing castration should be performed with both the surgeon and the handler positioned on the same side of the horse, usually the left side for the right-handed surgeon. The surgeon should be positioned at the horse’s shoulder well out of kicking range with his or her head and shoulder pressed firmly into the horse’s flank.

Standing castration can be performed safely and efficiently if candidates are selected prudently, if the horse is adequately sedated, if the spermatic cord and scrotum are properly desensitized with a local anesthetic agent, and if the surgeon is technically proficient. A standing castration requires less expense and assistance, and it is often less time consuming because the surgeon need not wait for the horse to recover from general anesthesia. Risks to the horse that attend general anesthesia are avoided. Because the spermatic cords and scrotum are locally desensitized, measures to rectify immediate postoperative complications, such as hemorrhage, can be accomplished without reanesthetizing the horse.

Recumbent Castration

ANESTHESIA
To castrate a horse in the recumbent position, a clean, safe area in which to anesthetize and recover the horse is a prerequisite. A variety of intravenous anesthetics, alone or in combination, can be administered to provide safe and predictable anesthesia of sufficient duration. A thiobarbiturate administered as a bolus produces rapid anesthesia characterized by moderate analgesia and muscular relaxation, particularly if the horse has been sedated with xylazine. Recovery is usually satisfactory if repeated administration of the thiobarbiturate is not necessary. Ketamine, administered after sedating the horse with xylazine, provides 10 to 15 minutes of surgical anesthesia. Muscular relaxation and analgesia are only moderate but can be enhanced if butorphanol tartrate or diazepam is added to the preanesthetic regimen. If necessary, anesthesia can be extended by administering half the dosage of xylazine and ketamine combined in one syringe. Guaifenesin (5% to 10%), in combination with ketamine or a thiobarbiturate, provides smooth induction and recovery and good analgesia with excellent muscular relaxation, but guaifenesin must be administered in large volumes. Succinylicholine, a muscle relaxant, has been widely employed as a chemical restraint for recumbent castration, but because it provides no analgesia, its use alone for castration is inhumane. Additional information on anesthesia can be found in Chapters 19 and 20.

POSITIONING
The horse is anesthetized and positioned in lateral recumbency with its upper rear limb pulled forward and secured with rope. The right-handed surgeon generally finds the
recumbent castration most easily performed with the horse positioned in left lateral recumbency, and vice versa.

**Approach**

**SCROTAL INCISION**

For the standing castration and one technique of recumbent castration, the testes are removed through a scrotal incision. If the horse is anesthetized, and if the testes are small and difficult to grasp, as is often the case with prepubescent stallions, the scrotum can be safely incised by pulling the cranial end of the prepuce craniad and upward to tense the scrotal raphe (Fig. 65-12). Another method of incising the scrotum is to compress the testes against the bottom of the scrotum. Two parallel 8- to 10-cm-long incisions are made 2 cm on either side of the raphe. The incision should be sufficiently long to provide adequate postoperative drainage. To ensure adequate drainage, many surgeons prefer to partially ablate the scrotum, which can be accomplished by connecting the two parallel incisions cranially and caudally and removing the portion of scrotum between the incisions.

Another method of removing the bottom of the scrotum is to grasp the scrotal raphe between the thumb and forefinger, and while applying traction to the bottom of the scrotum, to excise a portion of the tented tissue with a scalpel (Fig. 65-13). When surgery is performed with the horse standing, stab wounds to the horse or surgeon that could result from sudden movement by the horse are avoided by incising with a scalpel blade held between the fingers rather than attached to a handle. A large portion of

---

**Figure 65-13.** The bottom of the scrotum is removed by placing traction on the scrotal raphe with a thumb and forefinger and excising a portion of the tented tissue with a scalpel.
the scrotum should be excised to ensure adequate drainage. To avoid cutting large vessels, the dissection should remain close to the scrotal skin. The testes are then isolated using digital dissection.

**INGUINAL INCISION**

For the inguinal approach, the horse is anesthetized and positioned in dorsal recumbency. The superficial inguinal ring is exposed through an 8- to 15-cm skin incision (depending on the horse’s size) made directly over the superficial inguinal ring.

**EMASCULATORS**

The emasculator models most commonly used are the improved White’s, the Reimer, and the Serra emasculators (Fig. 65-14). The Reimer emasculator crushes the cord, and a separate handle and blade sever the cord distally. Because the cord is severed with a separate handle, there is no danger of cutting the cord before it is satisfactorily crushed. The extra handle on the Reimer emasculator makes the instrument somewhat unwieldy for standing castration. The jaws of the Serra emasculator are curved, so that the cord is evenly crushed, and the grooves on the crushing blades are oriented parallel to the cord, decreasing the chance of accidentally transecting the cord with the crushing portion of the jaws (Fig. 65-15). A type of emasculator used more commonly in Europe than in North America has no cutting component and only crushes the cord (Fig. 65-16). The cord must be severed distal to the crushed segment with a scissors or scalpel blade.

**Surgical Techniques**

Techniques of orchidectomy are the open, closed, and half-closed techniques, regardless of whether the horse is castrated while standing or recumbent, or whether the approach is inguinal or scrotal. With the open technique of castration, the parietal (or common vaginal) tunic is retained. With the closed and the half-closed techniques, the portion of the parietal tunic that surrounds the testis and distal portion of the spermatic cord is removed.

OPEN TECHNIQUE
When performing the open technique of castration, the parietal tunic of testis is incised. The ligament of the tail of the epididymis (caudal ligament of the epididymis), which attaches the parietal tunic to the epididymis, is severed or bluntly transected. By transecting the fold of the mesorchium and mesoepididymal, the testis, epididymis, and distal portion of the spermatic cord are completely freed from the parietal tunic and removed using an emasculator. The open technique of castration is probably the most commonly used technique.

CLOSED TECHNIQUE THROUGH A SCROTAL APPROACH
With the closed technique, the parietal tunic is not incised, so it also is removed along with the testis and a portion of the cord. Using digital dissection, the parietal tunic surrounding the testis is freed from the scrotal ligament and skin and a portion of the spermatic cord with one hand, the parietal tunic surrounding the cord is separated from fascia surrounding the spermatic cord with the other hand. After the parietal tunic is separated from the surrounding fascia, it and its contents are removed using an emasculator. Care should be taken, when separating the fascia from the spermatic cord, to include the large pudendal vessels that lie within the fascia, so that these vessels are not included in the jaws of the emasculator.

HALF-CLOSED TECHNIQUE
The closed technique just described can be converted to a half-closed technique by making a 2- to 3-cm vertical incision through the exposed parietal tunic at the cranial end of the testis or the distal end of the spermatic cord. A thumb (the left thumb if the operator is right-handed) is inserted through the incision into the vaginal cavity. The testis and a portion of the spermatic vasculature are prolapsed through the incision by applying downward traction on the tunic with the thumb while simultaneously using the fingers of the same hand to push the testis through the incision. The fundus of the parietal tunic inverts and follows the testis through the incision because of its attachment to the testis by the ligament of the tail of the epididymis. Traction is applied to the parietal tunic with the index and middle fingers, which are placed into the sac formed by the inverted fundus. Traction can also be applied to the parietal tunic and the testis by applying a large Carmalt or Allis forceps to the parietal tunic before prolapsing the testis from the vaginal cavity. The half-closed technique should be considered a closed technique because the parietal tunic is removed along with the testis and the distal portion of the spermatic cord.

For each technique, the emasculator is applied at a right angle to the spermatic cord, loosely closed to avoid incorporation of scrotal skin, and slid further proximally. The emasculator is applied so that the crushing component is proximal to the cutting blade. When correctly applied, the wing-nut of the emasculator is oriented distally toward the testis, and the emasculator is said to be positioned "nut to nut." This positioning is not critical when using an emasculator that does not have a cutting blade. The scrotal skin is pushed toward the abdomen with one hand (with the spermatic cord positioned between the index and middle fingers) toward the horse’s abdomen, and the jaws of the emasculator are inspected to ensure that they do not contain scrotal skin. The tension on the cord is relieved, and the handles of the emasculator are compressed completely to crush and sever the cord. The time that should elapse before the emasculator is removed from the spermatic cord depends on the size of the cord being severed and the dependability of the emasculator used, but applying the emasculator for about 1 minute is usually sufficient to achieve hemostasis. If the cord is exceptionally large, the emasculator can be applied for a longer time, or the parietal tunic and cremaster muscle can be crushed and severed separately from the testicular vessels and the ductus deferens. The cutting blade of the emasculator should not be so sharp that the cord is completely severed but rather should be slightly dull so that the cord must be torn, although with only slight effort, from the blade. If a noncutting emasculator is used, the cord is severed with a scalpel blade 2 to 3 cm distal to the emasculator. The emasculator should be elevated toward the horse’s inguinal area before the cord is released, so that the testicular vessels do not recoil. It is customary, and perhaps prudent, when performing a standing castration to leave the scrotal wound unsutured. Loose scrotal fascia protruding from the scrotal opening is trimmed with scissors.

A technique (i.e., the Zurich technique) frequently used in Europe to ensure adequate scrotal drainage involves suturing a 30-cm-long gauze drain to the stump of one of the cords with heavy catgut suture. The drain that exits the scrotal wound is removed 2 days after castration by rupturing the catgut suture with a sharp tug on the drain.

SELECTION OF TECHNIQUE
An advantage of the closed and half-closed techniques of castration is that removal of the parietal tunic decreases the incidence of postoperative complications, such as septic funiculitis and hydrocele (see “Postoperative Complications of Testicular Surgery,” p. 802). The half-closed technique permits inspection of the components of the cord and allows a greater portion of the ductus deferens and testicular vasculature to be exteriorized. For horses at risk of having an unapparent inguinal hernia, such as Standardbreds, eversion can be avoided by using a closed technique and placing a ligature proximal to the proposed site of transection.

The closed technique of castration has no advantage over the open technique in preventing evisceration if a ligature is not applied to the cord proximal to the site of transection. The closed and half-closed techniques are indicated for disease conditions that may involve the parietal tunic, such as neoplasia and orchitis. The closed and half-closed techniques require more dissection than does the open method of castration, and this may be a disadvantage when performing a standing castration on a fractious stallion.

Primary Closure of the Incision
By convention, scrotal incisions are usually left unsutured to heal by secondary intention. Primary closure, however, speeds healing and recovery, eliminates infection, and decreases edema, pain, and muscular stiffness. Primary closure may be particularly useful if vigorous exercise cannot be enforced postoperatively. Primary closure decreases...
convalescence but is time consuming and requires meticulous hemostasis and strict adherence to aseptic technique. In one study, no complications were encountered when the spermatic cords were simply transected with an emasculator.133 Hemorrhage from a cord into the sutured scrotum, however, even if only a small amount, risks formation of a hematoma, and therefore, ligation of the cord proximal to the point of division with the emasculator ensures good hemostasis and should be considered an important part of the procedure.

One investigator, pointing out the importance of eliminating dead space, closed the subcutaneous tissue with multiple rows of absorbable suture.133 Another investigator, however, found multiple-layer closure unnecessary and reported minimal postoperative complications when only the scrotal skin was sutured.138 The cutaneous incision is best closed with an absorbable 2-0 monofilament suture using a simple-continuous intradermal suture pattern. Because the cutaneous incision is sutured intradermally, removal of cutaneous sutures is not necessary.

The testes can be removed per primam through an inguinal incision created over each spermatic cord.133 This technique is frequently used in Europe when castrating horses 2 years old or older to avoid evisceration, because the vaginal rings of these horses are thought by some surgeons to be wider than those of younger horses. Using this technique, the inguinal fascia is separated digitally to expose the superficial inguinal ring. The fascia must be separated bluntly to avoid lacerating large branches of the external pudendal vessels. Blunt dissection is continued until the spermatic cord is encountered. The parietal tunic surrounding the cord is freed from surrounding fascia and incised longitudinally for 5 cm.

Using an index finger, the testicular vessels and ductus deferens are exteriorized through the incision, and using gentle traction on these structures, the testis is pulled from the vaginal cavity. The ligament of the tail of the epididymis, which attaches the testis to the parietal tunic, is identified and transected. Bleeding vessels are cauterized to prevent hemorrhage into the vaginal cavity. Two transfixing ligatures are applied 1 cm apart, as far proximally as possible, to the testicular vasculature and ductus deferens, using an absorbable, heavy monofilament suture. The vasculature and ductus deferens are severed 2 cm distal to the distal ligature, and the stump is replaced into the vaginal cavity. If this technique of per primam castration is performed with the expectation of preventing incarceration of intestine in the inguinal canal, a ligature should be applied to each spermatic cord proximal to the point of transection.136

The incision in the parietal tunic and the subcutaneous tissue are each sutured with an absorbable 2-0 monofilament suture using a simple-continuous pattern. The cutaneous incision is closed with the same suture using a simple-continuous intradermal suture pattern.

**Aftercare**

All horses not previously immunized with tetanus toxoid should receive both tetanus antitoxin and toxoid. The previously immunized horse should receive a booster vaccination if more than a year has passed since its last vaccination.137 The horse’s activity should be restricted for the first 24 hours after castration to avoid hemorrhage from the severed testicular and scrotal vessels. After this period, the horse should be exercised to the degree necessary to prevent excessive preputial and scrotal edema. A large, grass-covered field is an ideal environment for postoperative recuperation, but the owner should be cautioned that turning a horse into a field does not ensure that it will receive adequate exercise.

Antimicrobial treatment is probably unnecessary if clean surroundings are provided, but a survey of practitioners, undertaken to determine the type and frequency of complications that occur after castration, found that horses may be less likely to develop infection at the castration site if they receive perioperative antimicrobial treatment.133 The operative site can be hosed vigorously, if the horse permits it, to keep the scrotal wound clean, open, and draining, but this same survey found that horses that receive hydrotherapy after castration may be more prone to develop excessive swelling and infection of the scrotum.

Protecting the wound against flies is usually unnecessary, even during fly season, if the horse’s tail-hairs are long enough to reach the scrotal area. The horse should be isolated from mares for at least 2 days after castration. Ejaculates are highly unlikely to contain sufficient spermatozoa to cause impregnation after 2 days.138 The castration wound should be nearly healed by 3 weeks.

**Laparoscopic Castration**

Ligating and transecting the blood supply and ductus deferens of scrotal testes laparoscopically with the horse standing or anesthetized results in avascular necrosis of the testicular parenchyma with the testes in situ.139,140

The standing approach is preferred by most surgeons, when the horse is castrated laparoscopically. To safely insert a laparoscopic sleeve and cannula into the abdomen, the abdomen can be insufflated through a Veress needle, IV catheter, teat cannula, chest drain, or metal uterine catheter introduced into the abdomen through a stab incision created slightly dorsal to the crus of the internal abdominal oblique muscle, midway between the last rib and the tuber coxae. The abdomen can also be insufflated, using the same devices, through a stab incision created on the linea alba. The abdomen is insufflated using a gas, such as carbon dioxide, nitrous oxide, or helium, until the intra-abdominal pressure rises to 8 to10 mm Hg. Care should be taken to avoid insufflating the retroperitoneal space. After the abdomen is inflated, the insufflation device is removed, and a laparoscopic sleeve with a guarded trocar is inserted through an incision in the flank. The laparoscopic sleeve and guarded trocar can also be inserted safely, without insufflating the abdomen, by allowing air to enter the abdomen through a blunt cannula, such as a chest drain, inserted into the abdomen through the flank. Air entering the abdomen causes the viscera to fall away from the body wall, allowing safe introduction of the laparoscopic sleeve and trocar. The trocar is removed, and the laparoscope, which is attached to a fiberoptic light source and a video camera and viewing monitor, is introduced into the abdomen. The laparoscope is directed caudally to view the inguinal areas. A 10-mm-diameter instrument portal is created 8 to 10 cm cranioventral to the laparoscopic portal, and another is created 8 to
10 cm caudoventral to the laparoscopic portal. A third, 5-mm diameter instrument portal is created 8 to 10 cm caudodorsal to the laparoscopic portal.

The testicular vessels and ductus deferens are identified in the mesorchium as they course toward the vaginal ring. A ligating loop is placed through the 5-mm instrument portal, and a right-angle dissecting forceps is inserted through the cranioventral portal and the ligating loop. The ductus deferens and testicular vessels are grasped with the forceps. Using a bipolar cautery forceps placed through the caudoventral instrument portal, the ductus deferens and testicular vessels are coagulated distal to the forceps. The cautery instrument is removed and replaced with a laparoscopic scissors, which is used to transect the ductus deferens and spermatic vessel immediately distal to the site of coagulation. The ligating loop is now slid over the right-angle forceps onto the coagulated stump of the ductus deferens and testicular vessels, tightened, and tied, and the ends of the ligature are cut. After releasing the forceps, the stump is inspected for hemorrhage.

By elevating the small colon manually per rectum, the contralateral testis can be removed using the same portals and technique. Removing the contralateral testis using portals created on the contralateral side, however, may be faster and easier.

The testes, deprived of their blood supply, swell during the first week and then begin to decrease in size. The atrophied testes can be palpated in the scrotum for at least several months, but by 5 months the remnants are no longer palpable. Within 7 days after the testicular vessels are ligated, the concentration of testosterone falls to that expected of a horse with no functional testicular tissue. The epididymis remains viable, but because it has no contribution to masculine behavior, the horse behaves as a gelding. Swelling and discomfort observed after laparoscopic castration seem to be less severe than is seen after routine castration. A testis whose blood supply has been interrupted can revascularize, however, apparently by periarterial angiogenesis, before the testis becomes completely necrotic, resulting in preservation of stallion-like behavior. The owner should be warned of this uncommon complication.

**Vasectomy**

A stallion used for detecting estrous (i.e., a teaser stallion) can be vasectomized to render it incapable of ejaculating spermatozoa and thus from accidentally impregnating mares. A stallion can be vasectomyed through an incision created over each spermatic cord or through a single incision created over one testis. To transect a portion of the ductus deferens through a single incision in the scrotal area, the horse is anesthetized, positioned in dorsal or lateral recumbency, and the scrotum is prepared for surgery. A 2-cm, longitudinal, cutaneous incision is made on the medial aspect of one testis, and the incision is extended through the dartos and parietal tunic. The ductus deferens, which is identified as a white, 2- to 3-mm-diameter, cordlike structure, is exteriorized and separated for a length of several centimeters from its mesorchium, using a curved hemostat. Two ligatures of 2-0 absorbable or nonabsorbable suture are placed around the most proximal aspect of the exposed portion of the ductus deferens, and a third ligature is placed around the most distal aspect of the exposed portion of the ductus deferens. The segment of ductus deferens between the two proximal ligatures and the distal ligature is removed. Double-ligating the proximal end minimizes the likelihood of spontaneous reanastomosis and formation of a sperm granuloma.

The incision in the parietal tunic is sutured with an absorbable 2-0 suture using a simple-continuous pattern. The ductus deferens on the medial aspect of the other testis is then palpated through the cutaneous incision and exposed by incising the scrotal septum and overlying parietal tunic. A segment of the ductus deferens is exteriorized, ligated, and transected as described. The incision in the parietal tunic and the subcutaneous tissue are each sutured with an absorbable 2-0 suture using a simple-continuous pattern. The cutaneous incision is closed with the same suture using a simple-continuous intradermal suture pattern.

**Immunologic Castration**

Immunization against luteinizing hormone–releasing hormone (LHRH), a neuropeptide produced by the hypothalamus, was used in a cryptorchid stallion to decrease serum concentration of testosterone and immunization against gonadotropin-releasing hormone (GnRH) was used experimentally to suppress testicular function of entire stallions. Repeated immunization was necessary to maintain a sufficient binding titer for complete neutralization of LHRH or GnRH and inhibition of the reproductive endocrine axis. Immunization against GnRH caused decreased concentrations of testosterone and estrogen in the serum, diminished sexual behavior, and decreased testicular size, and it had a negative effect on semen quality. Stallions varied in response to immunization, and in one study, libido was not totally suppressed.

If a vaccine against LHRH or GnRH becomes commercially available, unwanted male sexual behavior by cryptorchid or entire stallions can be prevented temporarily. A vaccine against GnRH may enable a stallion to perform at its peak ability at athletic competitions, by decreasing undesirable sexual behavior, until the stallion’s genetic potential can be determined, while allowing the stallion to retain its ability to produce progeny. The time required for recovery of libido and semen quality needs to be determined before a vaccine against LHRH or GnRH is used clinically for temporary diminution of male sexual behavior.

**Cryptorchid Castration**

A retained testis can be removed through an inguinal, parainguinal, suprapubic paramedian, or flank approach. For each of these approaches, except the flank approach, the horse must be anesthetized. The approach is termed noninvasive if the testis can be removed by introducing only one or two fingers into the abdominal cavity, and an approach that requires insertion of a hand into the abdomen is considered invasive. Only the inguinal and parainguinal approaches allow noninvasive removal of a cryptorchid testis.
**Inguinal Approach**

For the inguinal approach, the horse is anesthetized and positioned in dorsal recumbency. The superficial inguinal ring is exposed through an elliptical, scrotal incision or through an 8- to 15-cm skin incision (depending on the horse’s size) made directly over the superficial inguinal ring. A cryptorchid testis and the contralateral scrotal testis (or two cryptorchid testes) can be removed from one incision if the incision is created over the scrotum rather than over the superficial inguinal ring.

The inguinal fascia is separated digitally to expose the superficial inguinal ring. An inguinal testis is readily encountered when the superficial inguinal ring is exposed. The vaginal sac should always be opened and its contents examined to avoid mistaking the descended tail of the epididymis of a partial abdominal cryptorchid for a small, inguinal testis. If the testis has already been removed, the stump of the spermatic cord is encountered as it exits the canal. Finding a stump of a severed ductus deferens, the remnant of spermatic vessels, and a well-developed cremaster muscle indicates that the horse has been castrated.\(^2\)\(^2\)\(^,\)\(^1\)\(^6\)

After the superficial inguinal ring has been exposed, an abdominal testis can be retrieved using one of several non-invasive techniques. One noninvasive technique requires locating the rudimentary common vaginal tunic, or vaginal process. This structure contains a portion the epididymis or sometimes a portion of the gubernaculum testis. The body of the epididymis can be exposed through a small incision in the vaginal process and traced to the tail of the epididymis, which is connected to the testis by the proper ligament of the testis. By placing traction on this ligament, the abdominal testis can be exteriorized through the vaginal ring. The key to this technique is locating the vaginal process. The vaginal process of the partial abdominal cryptorchid lies everted within the inguinal canal and is readily encountered during inguinal exploration. The vaginal process of the complete abdominal cryptorchid lies inverted within the abdominal cavity, along with the epididymis and testis, and difficulty may be encountered in locating and evertting it into the canal.

An inverted vaginal process can be everted into the inguinal canal by exerting traction on the scrotal ligament, which is also known as the inguinal extension of the gubernaculum testis (IEGT)\(^1\)\(^2\) (Fig. 65-17). This ligament is a remnant of the gubernaculum testis and attaches the vaginal process to the scrotum.

![Figure 65-17](image-url). An inverted vaginal process can be everted into the inguinal canal by exerting traction on the scrotal ligament, which is also known as the inguinal extension of the gubernaculum testis (IEGT). This ligament is a remnant of the gubernaculum testis and attaches the vaginal process to the scrotum.
PREVENTING EVISCERATION

The vaginal ring should be re-palpated after the abdominal testis is removed. If the ring accommodates no more than the tips of the index and middle fingers, the horse can be recovered, and unrestricted activity can be safely allowed after several days. If the ring has been dilated beyond this diameter, one of two measures must be taken to prevent eversion. To avoid eversion, the inguinal canal can be packed to the level of the vaginal ring with sterile gauze for 24 to 36 hours. The pack is maintained in the canal by partially suturing the skin incision. Eversion may follow removal of the pack, especially if gauze has been inadvertently inserted through the vaginal ring into the abdomen. Not only does gauze in the abdomen prevent the vaginal ring from contracting but it also becomes adhered to viscera. Eversion can be avoided by palpating the vaginal ring per rectum after the pack is inserted and before it is removed to ensure that gauze has not entered the abdomen. After the pack is removed, the horse's activity should be restricted to hand-walking for several days before forced exercise is imposed. Jumping, cantering, and galloping should not be allowed for 3 weeks.

Although the deep inguinal ring is inaccessible for suturing, the superficial inguinal ring can be closed with an interrupted or continuous pattern of heavy, absorbable suture to prevent eversion. A hernia or kidney needle is the needle of choice for suturing the inguinal ring. Not only does suturing the superficial inguinal ring provide better security against eversion than does packing the canal with gauze but it also allows primary closure of the inguinal fascia and skin. Although viscera can enter the inguinal canal, incarceration of intestine by the vaginal ring has not been reported. Inguinal fascia and skin can be sutured after closure of the superficial inguinal ring or allowed to heal by secondary intention. Activity should be restricted to hand-walking for several days before forced exercise is imposed. Heavy exercise should not be allowed for 3 weeks after surgery.

Parainguinal Approach

If the vaginal process cannot be located using the previously described techniques, the testis can be removed noninvasevively by converting the inguinal approach to a parainguinal approach. A 4-cm incision is made in the aponeurosis of the external abdominal oblique muscle, 1 to 2 cm medial and parallel to the superficial inguinal ring. The incision is centered over the cranial aspect of the ring. The internal abdominal oblique muscle underlying the aponeurosis is spread in the direction of its fibers, and the peritoneum is penetrated with a sharp thrust of the index and middle fingers. The vaginal ring is palpated caudolateral to the point of entry into the abdomen. The epididymis, ductus deferens, and gubernaculum are situated near the ring, and by sweeping the region with a finger, one of these structures can be grasped between the index and middle fingers and exteriorized. The body of the epididymis is followed to the tail. Traction on the proper ligament of testis pulls the testis through the incision.

If difficulty is encountered in locating the epididymis or associated structures, or if exteriorizing the testis is difficult, the incision can be enlarged to accommodate a hand. After excising the testis, the incision in the aponeurosis of the external abdominal oblique muscle is apposed using heavy absorbable sutures in an interrupted or continuous pattern. The subcutaneous tissue and skin can be sutured or left unapposed to heal by secondary intention. The horse can
receive exercise after surgery, excluding cantering and galloping, provided that the parainguinal incision was short enough that it could accommodate only several fingers. Unrestricted activity is allowed 3 weeks after surgery.\textsuperscript{146} The parainguinal approach is preferred over the inguinal approach by some surgeons because the vaginal ring is not disrupted.\textsuperscript{146} The aponeurosis of the external abdominal oblique muscle is more easily sutured than the superficial inguinal ring.

\textbf{Suprapubic Paramedian Approach}

For the suprapubic paramedian approach, an 8- to 15-cm, longitudinal skin incision is made 5 to 10 cm lateral to the ventral midline.\textsuperscript{147,149} The incision begins at the level of the preputial orifice and extends caudally. The large subcutaneous vessels encountered caudally in the incision are ligated. The abdominal tunic and the closely adherent ventral sheath of the rectus abdominis muscle are incised longitudinally, and the underlying fibers of the rectus
abdominis muscle are bluntly separated in the same direction. The dorsal rectus sheath, retroperitoneal fat, and peritoneum are penetrated with a finger. The perforation is bluntly enlarged, and a hand is introduced into the abdomen.

The testis is usually encountered near the vaginal ring. If the testis cannot be palpated, accessory structures at the vaginal ring can be located and followed to the testis, or the ductus deferens can be found in the genital fold of the bladder and traced to the testis. Both testes of a bilateral cryptorchid can be removed through one incision, but the contralateral testis is difficult to exteriorize, and its cord usually must be transected with an écraeer. After removing the testis, the abdominal tunic, the subcutis, and skin are each closed separately with interrupted or continuous sutures.

**Figure 65-19.** Cryptorchid testis. b, body of epididymis; cle, caudal ligament of the epididymis; ct, cryptorchid testis; d, ductus deferens; h, head of epididymis; plt, proper ligament of the testis; pt, parietal tunic; t, tail of epididymis; tv, testicular vessels.

**Figure 65-20.** With traction on the proper ligament of the testis, the testis is pulled through the vaginal ring.

**Figure 65-21.** Parainguinal approach to cryptorchidectomy. A 4-cm incision is made in the aponeurosis of the external abdominal oblique muscle 1 to 2 cm medial and parallel to the superficial inguinal ring. The incision is centered over the cranial aspect of the ring.

**Figure 65-22.** Parainguinal approach to cryptorchidectomy. The vaginal ring is palpated caudolateral to the point of entry into the abdomen. Either the epididymis, gubernaculum, or ductus deferens is located at the vaginal ring and exteriorized.
Flank Approach

For the flank approach, a 10- to 15-cm incision is made through the skin and subcutis in the paralumbar fossa of the affected side with the horse standing or recumbent. In a standing horse, the incision site must be anesthetized before the surgery. The external abdominal oblique muscle is transected in the direction of the skin incision, and the peritoneum is exposed by splitting the internal abdominal oblique and transversus abdominis muscles in the direction of their fibers. The peritoneum and retroperitoneal fat are perforated with a finger to enter the abdomen. The testis is located and exteriorized as described for the paramedian approach. If the testis cannot be exteriorized, an écraseur is used to transect the testicular vasculature. After the abdominal testis is removed, the internal and external abdominal oblique muscles, subcutis, and skin are each closed separately with interrupted or continuous sutures. Closing the peritoneum and transversus abdominis muscle is difficult and not necessary.

Selection of Approach

The paramedian and flank approaches allow removal of only an abdominal testis, because retraction of an inguinal testis into the abdomen can usually be accomplished only with difficulty. Abdominal testicular retention should be confirmed before either of these approaches is used, but often testicular location cannot be determined reliably. The inguinal approach allows removal of either an abdominal or an inguinal testis. Because an inguinal testis is quickly encountered using an inguinal approach, prior determination of testicular location is not necessary. If the testis is not encountered in the inguinal canal using an inguinal approach, the testis can be removed from the abdomen noninvasively through the vaginal ring or through a small parainguinal incision in the abdominal musculature.

Because the inguinal and parainguinal approaches allow removal of an abdominal testis through a finger-size abdominal perforation, surgery is rapid, and convalescence is short. The lengthy incision required for the suprapubic paramedian and flank approaches prolongs surgery and convalescence. The paramedian approach also increases the risk of postoperative evisceration or herniation. Rarely, an invasive approach is necessary to remove a large, neoplastic, or infected testis. An abdominal testis can be removed with the horse standing using a flank approach, when general anesthesia is not practical.

Laparoscopic Technique of Cryptorchidectomy

An abdominal testis can be removed laparoscopically with the horse standing or recumbent, but fractious stallions should be anesthetized. Food should be withheld for at least 12 hours before surgery to allow the colon to empty, to decrease the risk of penetrating a viscus when instruments are introduced, and to optimize visualization of intra-abdominal structures.

To perform laparoscopic removal of an abdominal testis with the horse standing, the horse is restrained in stocks and sedated. The flank region is prepared for surgery, and proposed sites for inserting the laparoscope and grasping forceps are infiltrated subcutaneously and intramuscularly with a local anesthetic agent. The surgical approach is identical to the one described for laparoscopic castration.

The testis is located by inspecting the region surrounding the vaginal ring. The vaginal ring and associated structures are easier to see when the horse is standing than when it is anesthetized and recumbent, because the abdominal contents fall away from the inguinal area. The contralateral vaginal ring can be observed by manipulating the laparoscope under the descending colon, or by passing the laparoscope through a small perforation created in the mesocolon of the descending colon, or by elevating the descending colon, either with an instrument placed through an abdominal portal or with a hand per rectum. The mesorchium, which contains the testicular vasculature, can be seen coursing caudally from the area of the kidney to the area of the deep inguinal ring. An abdominal testis can be observed to lie anywhere between the kidney and the vaginal ring, but most commonly it is located cranioventral to the ring. The testis is attached to the tail of the epididymis by the proper ligament of the testis, and the epididymis is attached to the vaginal ring and sac by the caudal ligament of the epididymis (ligament of the tail of the epididymis). The testis and mesorchium are desensitized by injecting a local anesthetic agent into the mesorchium or the testis, using a 30-cm-long, 18-gauge needle introduced through the flank. Desensitizing the testis and mesorchium may not be necessary, especially if caudal epidural anesthesia, using either a combination of 2% mepivacaine (5 mL) and xylazine (0.18 mg/kg), or xylazine (0.18 mg/kg) diluted to 10 to 15 mL with physiologic saline solution, is administered before surgery. An instrument portal close to the vaginal ring is created caudal and ventral to the laparoscopic portal. The testis is grasped and exteriorized using grasping forceps inserted through this portal. If triangulation is inadequate, a new portal for the laparoscope can be created between the last two ribs using laparoscopic control. The testicular vessels and ductus deferens are ligated and cut, or crushed and transected using an emasculator, and the stump is returned to the abdomen and inspected through the laparoscope for hemorrhage. If the contralateral testis is also located abdominally, the laparoscopic procedure is repeated on the contralateral side. The abdomen is decompressed by opening the cannula. The abdominal fascia and skin are sutured.

The testicular vessels and ductus deferens of an abdominal testis can also be transected intra-abdominally, with the horse standing, before removing the testis. This technique requires the use of a third portal, created close to the other portals, to introduce instruments used to occlude and transect the testicular vasculature and ductus deferens. The scrotal testis of a unilateral cryptorchid or an inguinal testis is removed through a scrotal incision, or its ductus deferens and vasculature can be ligated and severed intra-abdominally, which causes the testis to atrophy in the scrotum or inguinal canal. Palpable but nonfunctional remnants of the testis may be detectable in the scrotum several months after the testis is destroyed by ligation of the testicular artery and vein. A scrotal testis of a juvenile stallion or an inguinal testis can be retracted into the abdomen for intra-abdominal transection of the ductus deferens and testicular vessels. The testis is retracted into the abdomen by placing traction on the mesorchium, after enlarging the
vaginal ring with scissors. retracting the testis into the abdomen inverts the vaginal tunic into the abdomen and the exposed ligament of the tail of the epididymis, which attaches the vaginal tunic to the tail of the epididymis, is severed. The incision in the vaginal ring can be closed with staples or left open.140,157

To perform laparoscopic removal of an abdominal testis with the horse anesthetized, the horse is positioned in dorsal recumbency.154-153 Laparoscopy may be particularly useful in evaluating a horse that displays stallion-like behavior but has the appearance of a gelding, especially when the presence or absence of testicular tissue cannot be determined conclusively by hormonal assay.152 Laparoscopy is also useful for removing an abdominal testis when the side of the testicular retention is not known.

A disadvantage of laparoscopic cryptorchidectomy is the expense of the equipment.150-152 A viscus, a large vessel, or the spleen can be penetrated inadvertently if the instruments are not inserted carefully into the abdomen.150,153 Improper use of electrosurgical coagulation during the procedure may also result in perforation of a viscus.157 If the procedure is performed with the horse anesthetized, the hindquarters must be elevated to displace the viscera cranially, making positive-pressure ventilation necessary. Familiarity with laparoscopic equipment and experience in laparoscopic techniques are required.

Repair of Inguinal Hernias and Ruptures
Nonsurgical Management

The majority of inguinal hernias are congenital, cause no distress, and spontaneously reduce by the time the foal is 3 to 6 months old.52,162 Repeated manual reduction may encourage spontaneous reduction, and applying a truss after manually reducing the hernia may speed resolution.75 To apply a truss, the foal is sedated and positioned in dorsal recumbency. The hernia is reduced, and the superficial inguinal ring is packed with rolled cotton. The cotton is maintained within the ring with elastic gauze and tape wrapped over the back and over both inguinal rings in a figure-eight (Fig. 65-23). The bandage can be left in place for up to a week. Surgical reduction of a congenital inguinal hernia is not necessary unless contents of the hernia become incarcerated or unless the hernia fails to regress.

Horses with an acquired inguinal hernia or an inguinal rupture usually require immediate treatment, because the intestine that has escaped through the vaginal ring or hole in the peritoneum is likely to become strangulated. Nonsurgical reduction of inguinal hernias by external
Surgical Management

A congenital inguinal hernia of a foal should be reduced surgically if the hernia cannot be reduced, has escaped into subcutaneous tissue through a rent in the vaginal sac, fails to resolve or enlarges, or is so large that spontaneous resolution is unlikely. To surgically correct inguinal herniation, the foal is anesthetized and positioned in dorsal recumbency. An incision is made directly over the superficial inguinal ring of the affected side, and the vaginal sac is isolated from surrounding fascia using blunt dissection. The scrotal ligament, which attaches the vaginal sac to the scrotum, is transected. While applying traction to the testis, the intestinal contents of the vaginal sac are milked back into the abdomen. Twisting the spermatic cord may facilitate replacement of intestine into the abdomen. The cord is ligated and resected proximal to the superficial inguinal ring. Ligating the cord prevents re-herniation, but for added security, the superficial inguinal ring can be closed with absorbable suture placed in a continuous or interrupted pattern. The skin and subcutaneous tissue can be left open to heal by secondary intention or closed primarily.

Nonstrangulating congenital inguinal hernias of foals can be corrected using laparoscopic technique. The contents of the hernia are reduced into the abdominal cavity laparoscopically, with the foal anesthetized, and the testis of the affected side is retracted from the vaginal cavity into the abdominal cavity and removed, after ligating and transecting the testicular vessels and ductus deferens. The vaginal ring is closed using a laparoscopic stapling device. The testis of the nonaffected side can also be removed in this manner. Nonstrangulating congenital inguinal hernias can be corrected using a similar laparoscopic technique without removing the testes. Advantages of laparoscopic herniorrhaphy are the quickness of the procedure and the rapid return of the foal to normal activity.

Emergency surgery is usually indicated for horses with an inguinal rupture or a ruptured inguinal hernia and for horses with an acute inguinal hernia that cannot be reduced by nonsurgical manipulation. Surgical correction of inguinal hernias is always indicated if viability of the testis or incarcerated intestine is questionable, because surgery allows these structures to be assessed visually.

Fluids should be administered intravenously in volumes sufficient to combat shock. The horse should be positioned in dorsal recumbency, and the ventral aspect of the abdomen and inguinal area should be prepared for aseptic surgery. The vaginal sac and its contents are exposed and isolated by blunt dissection through an incision created over the superficial inguinal ring. The vaginal sac is opened to expose its hernial contents and the testis. Devitalized intestine may be resected at the inguinal wound, but resection and anastomosis are usually more easily accomplished through a celiotomy. Dilating the vaginal ring and applying traction to the intestine through a ventral midline, para-median, or parainguinal celiotomy may assist reduction of the herniated intestine. The affected testis should be removed if it appears nonviable or even if its viability is questionable.

If the testis is removed, re-herniation through the inguinal canal can be prevented by ligating the spermatic cord and the vaginal tunic as proximally as possible with absorbable suture. For additional security, the inguinal canal...
can be packed with gauze for 24 to 48 hours, or the superficial inguinal ring can be closed with heavy absorbable suture. Suturing the superficial inguinal ring gives greater security against re-herniation than does packing the inguinal canal. The inguinal fascia and skin can be closed primarily or left unsutured to heal by secondary intention. The celiotomy is closed in routine fashion.

Reherniation through the inguinal canal can be prevented, while at the same time trying to preserve a viable testis, by partially suturing the superficial inguinal ring around the spermatic cord. Suturing starts at the cranial aspect of the ring and ends near the middle of the ring to give a snug, but not tight, closure around the spermatic cord. Difficulty arises in closing the ring adequately to prevent re-herniation while still maintaining blood supply to the testis. A more certain method of salvaging the testis is laparoscopic inguinal herniorrhaphy. One method of laparoscopic inguinal herniorrhaphy entails implanting a polypropylene mesh beneath the peritoneum over the deep inguinal ring and the duc tus deferens and testicular vessels that enter it, with the horse anesthetized and in the Trendelenburg position. A less sophisticated but apparently effective technique of laparoscopic inguinal herniorrhaphy involves inserting a coiled polypropylene mesh through the enlarged vaginal ring into the inguinal canal. The coiled mesh is pushed into the inguinal canal until the proximal edge of the mesh is distal to the vaginal ring and allowed to uncoil. The mesh is fixed to the inguinal canal with endoscopic staples. Fibrous reaction to the mesh obliterates the canal, preventing intestine from entering it. The procedure can be performed with the horse standing.

**SPECIAL CONSIDERATIONS**

**Hemicastration**

Fertility is maintained after hemicastration of normal horses. Testes undergo compensatory hypertrophy after hemicastration in response to increased secretion of interstitial cell–stimulating hormone from the hypophysis. A hydrocele, neoplasia, or orchitis of one testis can cause temperature-induced dysfunction of spermatogenesis of the other testis, but removing the diseased testis may allow the remaining testis to regain normal spermatogenesis.

Postponing removal of the diseased testis can result in permanent dysfunction of the nondiseased testis.

The descended testis of a cryptorchid should never be removed without first removing the nondescended testis. Failure to find and remove the nondescended testis after the descended testis has been removed enables an unscrupulous owner to fraudulently represent the horse as a gelding and may complicate subsequent surgery, especially if there is no written record of which testis was removed. Compensatory hypertrophy of the nondescended testis occurs after hemicastration and may complicate removal of an abdominal testis. Removing the descended testis has been advocated to promote descent of the cryptorchid testis, but descent of an abdominal testis becomes impossible within several weeks after birth. There is no proof that hemicastration actually results in descent of an inguinal testis. An inguinally retained testis is located easily during inguinal exploration and should be removed along with the descended testis.

**Hormonally Induced Testicular Descent**

Because testicular descent is hormonally controlled, treatment of a horse for cryptorchidism with hormones would seem to be an attractive mode of therapy. Hormonal factors responsible for testicular descent are still obscure, however, and no specific therapy has been developed to correct the hormonal defect responsible for testicular retention. GnRH and hCG have been administered separately and in combination to bring about testicular descent, but evidence of efficacy is lacking. If a cryptorchid testis of a human descends into the scrotum or is surgically placed in the scrotum, degenerative changes within the testis can reverse so that the testis becomes capable of producing sperm, but for degenerative changes to reverse, the cryptorchid testis must enter the scrotum while the child is very young.

The age of the horse at which a cryptorchid testis must descend into the scrotum to contribute to fertility has not been determined.

After the first few weeks of neonatal life, the vaginal rings contract, reducing the likelihood of descent of an abdominal testis. Hormonal therapy, therefore, is likely to have no effect on descent of an abdominal testis. Testicular growth, brought about by onset of puberty, may bring about descent of an inguinal testis, and this supports the rationale for administration of GnRH or hCG. The effect of exogenous hormones on descent of inguinal testes, however, is unclear. Because genetic studies of equine cryptorchidism indicate that testicular retention is probably hereditary, hormonal therapy to bring about testicular descent is no more ethical than surgically placing the testis in the scrotum.

**POSTOPERATIVE COMPLICATIONS OF TESTICULAR SURGERY**

**Hemorrhage**

Excessive hemorrhage is usually the result of an emasculator that is improperly applied or is in imperfect working order. Reversing the emasculator (i.e., placing the cutting edge toward the abdomen) usually results in severe hemorrhage, because the cord is crushed distal to the site of transection. The emasculator should be applied perpendicular to the cord, because transection of the cord other than at a right angle increases the diameter of the severed ends of the testicular vessels. The blade of the emasculator should not be so sharp that the testicular vessels are severed before they are crushed properly. A blade that is too sharp can be dulled by using it several times to cut rope.

The testicular vessels may be insufficiently crushed if scrotal skin is inadvertently included in the emasculator’s jaws. The thick cords of a mature stallion may require double emasculation to sufficiently crush the vessels. Using this technique, the parietal tunic and cremaster muscle are crushed and transected separately from the testicular vessels and duc tus deferens.

A ligature placed around the entire spermatic cord or around the testicular vessels alone can be used alone, or in conjunction with an emasculator, to prevent hemorrhage. Although a ligature, with or without an emasculator, may be more effective than the emasculator alone in preventing hemorrhage, the use of a ligature may increase the incidence
of infection at the surgery site.\textsuperscript{129} The increase in risk of infection associated with the use of a ligature is likely to be the result of reduced resistance of tissue contaminated with bacteria to infection in the presence of foreign material, especially if a nonabsorbable suture is used.

Dripping of blood from the wound for several minutes after emasculation is expected and should cause no concern. Unabated streaming of blood for 15 to 30 minutes is a signal for alarm. The testicular artery is the usual source of severe hemorrhage.\textsuperscript{20} Because testicular veins are valved, hemorrhage from these vessels is usually mild. Hemorrhage from scrotal vessels is usually not serious and soon ceases spontaneously. If, after allowing the horse to stand quietly for 15 to 30 minutes, hemorrhage does not diminish, the end of the cord can be grasped using fingers and stretched to allow application of a crushing forceps or an emasculator. A crushing forceps with curved jaws, such as a kidney clamp, is easier to apply and maintain in position than a straight forceps. If the horse was castrated while standing, the end of the cord is likely to still be desensitized, and the forceps or emasculator can usually be applied without causing serious discomfort to the horse. The forceps is removed the next day. If the horse was castrated while recumbent, the cord is not desensitized, so to safely grasp and crush the end of the cord, the horse may need to be reanesthetized.

If the end of the cord is inaccessible through the scrotal incision, hemorrhage can be stopped by ligating the testicular vessels intra-abdominally using the procedure described for laparoscopic removal of an abdominal testis.\textsuperscript{173,174} Laparoscopic surgery to stop hemorrhage after castration can be performed with the horse standing or anesthetized and positioned in dorsal recumbency. The testicular artery can be coagulated using electrocoagulation, or occluded with a laparoscopic suture loop or a vascular clip.

If the end of the cord is inaccessible, and if intra-abdominal ligation of the testicular vessels using laparoscopy is not an option, sterile gauze can be packed tightly into the inguinal canal and scrotum, and the scrotum closed with sutures or towel clamps. The pack is removed the next day. Ten percent formalin (i.e., a 4% aqueous solution of formaldehyde gas created by diluting a 37% to 40% solution of formaldehyde gas with 9 parts of water) has been used with questionable success to stop hemorrhage. In one study, 8 to 16 mL of 4% to 12% formaldehyde solution administered intravenously to average-size horses decreased time of coagulation by 67% for 24 hours.\textsuperscript{175} However, another study demonstrated no variation in time of coagulation after intravenous administration of formaldehyde solution.\textsuperscript{176} Formaldehyde solution is pyretogenetic and accelerates pulse and respiration.\textsuperscript{175} Other side effects include restlessness, lacrimation, salivation, elevation of the tail, nasal discharge, increased peristalsis with frequent defecation, sweating, quivering of muscles, signs of severe abdominal pain, and tenesmus. Physical reaction is minimal when 10 mL of 4% formaldehyde solution (i.e., 10% formalin), diluted in a liter or more of physiologic saline solution, is administered intravenously. This author has observed dramatic reduction of hemorrhage, with no clinically apparent side effects, within minutes after intravenously administering this amount, but convincing scientific evidence of the safety and efficacy of a formaldehyde solution in reducing hemorrhage is lacking.

**Evisceration**

An uncommon but potentially fatal complication of castration is evisceration through the vaginal ring and open scrotal incision. Horses that eviscerate after castration may have a pre-existing, unapparent, congenital, inguinal hernia.\textsuperscript{56} Most unapparent inguinal hernias resolve by the time the horse is 3 to 6 months old,\textsuperscript{164} so horses castrated before they are 6 months old may be at greater risk of eviscerating after castration than are horses castrated after they are 6 months old. Standardbreds and Draft Horses may be more frequently affected by postoperative evisceration, because they have a higher incidence of congenital inguinal herniation.\textsuperscript{129,136} Based on anecdotal evidence and unpublished data, Tennessee Walking Horses and American Saddlebreds may also have a higher incidence of congenital inguinal herniation and so may be predisposed to evisceration after castration.\textsuperscript{177}

To decrease the likelihood of evisceration after castration, the horse’s inguinal area should be palpated for the presence of an inguinal hernia before the horse is castrated, and the owner should be questioned as to whether the horse suffered from a congenital inguinal hernia as a foal. If the horse has or has had an inguinal hernia, is less than 6 months old, or is a member of a breed that has an increased incidence of inguinal herniation, the surgeon should consider taking measures to prevent evisceration. Some clinicians examine the vaginal rings per rectum before castrating a horse deemed to be at risk for evisceration because of its breed.\textsuperscript{178} The vaginal ring of stallions is normally large enough to accommodate the tip of one finger. According to some clinicians, precautions to prevent evisceration should be taken if a vaginal ring is larger than two fingers. The risk of rectal injury should be weighed against the value of the diagnostic information to be gained before performing examination of the vaginal rings per rectum.

For horses that have a higher than normal risk for evisceration, castration should be performed with the horse anesthetized. The testes should be removed using a closed technique, and the spermatic cord should be ligated. The cremaster muscle should be isolated from the cord before the cord is ligated, so that it is not included in the ligature. Including the cremaster muscle in the ligature could cause the ligature to loosen when the cremaster muscle contracts. The closed technique of castration does not diminish the incidence of evisceration unless a ligature is applied to the cord proximal to the site of transection.\textsuperscript{136}

Evisceration usually occurs within 4 hours after castration and may be precipitated by attempts to rise from anesthesia.\textsuperscript{56,179} Evisceration has occurred up to 6 days after castration,\textsuperscript{56} and one horse was reported to have herniated into its sutured scrotum and vaginal cavity 12 days after castration.\textsuperscript{180} After intestine enters the canal, peristalsis encourages further protrusion, and intestinal strangulation accompanied by severe signs of colic rapidly ensues. Treatment of a horse that has eviscerated through the inguinal canal is similar to emergency treatment of horses with acquired inguinal herniation. The horse should be anes-
Edema

Preputial and scrotal edema develops after nearly every castration and is generally greatest around the fourth postoperative day. Excessive edema, reported to be the most common complication of castration, can usually be avoided by removing a generous portion of the scrotum during castration and by vigorously exercising the horse for several weeks to promote drainage from the open wound. Without vigorous exercise, the scrotal skin may seal and trap fluid containing bacteria or inflammatory products within the scrotal cavity. Excessive edema can usually be relieved by opening the sealed wound with scrotal massage or by inserting a gloved finger into the scrotal cavity and enforcing vigorous exercise. High-pressure lavage of the scrotal wound with tap water administered using a garden hose may assist in keeping the wound open and clean, but a survey of practitioners (performed to determine the type and frequency of complications that occur after castration) indicated that horses that receive hydrotherapy after castration may be more prone to develop excessive swelling and infection of the scrotum.

Septic Funiculitis

A scrotal wound, like any other wound left unsutured to heal by secondary intention, becomes contaminated and may subsequently become infected. The infection remains confined to the scrotal cavity as long as the scrotal incision remains open and draining, and it resolves as the scrotum heals. Septic funiculitis, or infection of the spermatic cord, can occur from extension of the scrotal infection, especially if the scrotal cavity does not properly drain. Septic funiculitis can also be caused by a contaminated emasculator or ligature. The open method of castration, in which the vaginal tunic and cremaster muscle are not removed, may predispose the horse to septic funiculitis. The condition is characterized by preputial and scrotal edema, pain, pyrexia, and sometimes lameness. Septic funiculitis may resolve with antimicrobial therapy and re-establishment of drainage, but occasionally, removal of the infected stump is required, especially if the cord has been ligated.

Champignon (French for “mushroom”) is a term used to describe a type of septic funiculitis of the stump of the cord caused by infection with Streptococcus. Champignon is characterized by purulent discharge and a mushroom-shaped mound of granulation tissue that protrudes from the scrotal incision. This was a common complication of castration before the invention of the emasculator, when hemorrhage was controlled by ligatures or “clams,” but now its importance is mostly historical. A stump chronically infected with pyogenic bacteria is commonly referred to as a scirrhous cord. Scirrhous cord, caused by Staphylococcus, is sometimes referred to as botryomycosis. The scrotal incision of a horse affected with septic funiculitis may eventually heal, but if the septic funiculitis does not resolve, the cord enlarges with granulation tissue and abscesses, which may eventually discharge through sinus tracts. The cord is hard, often painless, and adhered to scrotal skin. The stump may become so large that it mechanically interferes with locomotion of the rear limb. In extreme cases, infection may ascend the cord into the abdomen, where a hard mass can be palpated per rectum at the deep inguinal ring. Occasionally, the lesion does not become apparent for several years after castration. Treatment is removal of the infected mass. The horse is anesthetized and positioned in dorsal recumbency. An incision is made over the superficial inguinal ring, and the infected cord is isolated from normal tissue (Fig. 65-25). The cord is transected proximal to the mass, using an...
emasculator or écraseur, and the wound is left unsutured to heal by secondary intention.

Clostridial Infection
Clostridial infection of the castration wound is particularly severe, because tissue necrosis and toxemia produced by clostridial organisms may lead to death within several days. Specific systemic signs of clostridial infection vary according to the clostridial species involved. *Clostridium tetani* causes general spasms and paralysis of the voluntary muscles. Horses develop a characteristic “saw-horse” stance and protrusion of the third eyelid.183 *Clostridium botulinum* causes flaccid paralysis, and early signs include decreased tone of the eyelids and tail, weakened gait, muscular tremors, and dysphagia.184 *Clostridium septicum*, *Clostridium perfringens*, *Clostridium chauvoei*, and *Clostridium fallax* have been identified as etiologic agents of malignant edema, a highly fatal disease characterized by fever, depression, toxemia, subcutaneous accumulation of gas, and fulminating cellulitis.185 Treatment of horses for clostridial infection at the castration site includes administration of high doses of penicillin and nonsteroidal anti-inflammatory and analgesic drugs, supportive therapy, radical débridement of all necrotic scrotal tissue, and establishment of scrotal drainage. Horses infected with *C. botulinum* and *C. tetani* can also be treated with antitoxin.184,186

Septic Peritonitis
Subclinical, nonseptic peritonitis occurs in many horses after castration because the peritoneal and vaginal cavities communicate.187 Postoperative, intra-abdominal hemorrhage may be responsible, at least in part, for nonseptic peritonitis, because free blood in contact with the peritoneum causes inflammation.188 A concentration of nucleated cells greater than 10,000/µL in the peritoneal fluid indicates peritoneal inflammation. A concentration greater than 10,000/µL can be found routinely in peritoneal fluid for at least 5 days after uncomplicated castration, and a concentration greater than 100,000/µL is not uncommon.187 Septic peritonitis occurs when peritoneal inflammation is accompanied by bacterial infection. Signs of septic peritonitis include colic, pyrexia, tachycardia, diarrhea, weight loss, and reluctance to move.189 Septic peritonitis should not be diagnosed on the basis of the concentration of nucleated cells in the peritoneal fluid alone, because a concentration greater than 10,000/µL merely indicates that the peritoneum is inflamed.187 The presence of degenerated neutrophils or intracellular bacteria in the peritoneal fluid is more indicative of bacterial peritonitis, especially when accompanied by clinical signs.190 Treatment of horses for septic peritonitis includes administration of antimicrobial and nonsteroidal anti-inflammatory and analgesic drugs, supportive therapy, and peritoneal lavage. Proper drainage of the scrotum must be established. The occurrence of septic peritonitis after castration is rare, perhaps because the funicular portion of the vaginal process is collapsed as it courses obliquely through the abdominal wall,191 and because mesothelial cells of the vaginal process are phagocytic.68

Penile Damage
The surgeon may encounter the shaft of the penis while separating scrotal fascia in search of an inguinal testis and, if inexperienced in orchidectomy, may mistake it for the testis. A portion of the shaft of the penis may be stripped of fascia, partially exteriorized, and amputated before its true identity is recognized (Fig. 65-26). Even if the penile shaft is recog-

Figure 65-25. The exteriorized portion of the spermatic cord is thickened and hardened from infection. The demarcation between normal and abnormal portions of the cord is obvious. A thick, hard, infected cord after castration is commonly referred to as a scirrhouc cord.

![Figure 65-25](image-url)

Figure 65-26. Stump of penis emerging from a scrotal incision. Much of the shaft of the penis was inadvertently removed during a standing castration.

![Figure 65-26](image-url)
nized before the penis is damaged, damage to the penile fascia created by dissection can result in excessive edema and even paraphimosis. Damage to the urethra during sharp dissection results in severe necrosis of tissue from extravasation of urine into surrounding tissue.\textsuperscript{192,193} Penile damage is easily avoided if the surgeon possesses some familiarity of genital anatomy and proper techniques of castration.

Excessive edema after castration can result in protrusion of the penis from the preputial cavity, and if the protruded penis is improperly cared for, its integument can be irreparably damaged. Prolonged penile protrusion can result in permanent penile paralysis.\textsuperscript{166} Administering a phenothiazine-derivative tranquilizer as a preanesthetic agent can result in priapism or penile paralysis. Penile paralysis and priapism are described in detail in Chapter 66.

**Hydrocele (Vaginocele)**
A hydrocele, or vaginocele, is a fluid-filled, painless swelling in the scrotum that may appear months or years after castration and is the result of the accumulation of sterile, amber-colored fluid in the vaginal sac.\textsuperscript{26} The fluid can often be reduced into the abdomen. The condition is uncommon and idiopathic, but open castration predisposes to the condition because the vaginal tunica is not removed. Hydroceles may occur more frequently in mules than in horses after castration.\textsuperscript{194} Enlargement of the scrotum with fluid may give the horse the appearance of an entire stallion, or the horse may appear to have an inguinal hernia.

If the hydrocele does not increase in size, is not aesthetically displeasing to the owner, and does not inconvenience the horse, no treatment is necessary; otherwise, the hydrocele should be surgically removed. Drainage only temporarily alleviates the condition. To remove the hydrocele, the horse is anesthetized, placed in dorsal recumbency, and prepared for aseptic surgery. Skin is incised directly over the fluid-filled vaginal sac, the sac is bluntly separated from adherent fascia, and the scrotal ligament, which attaches the vaginal sac to the scrotum, is severed. The sac is transected, using a scissors or an emasculator, as proximally as possible. The wound can be sutured or left open to heal by secondary intention.

**Continued Masculine Behavior**
Castration is not always successful in completely eliminating objectionable masculine behavior, and some geldings may display sexual behavior, such as genital investigation, erection, mounting, and even copulation. Objectionable masculine behavior of geldings is especially common in spring and early summer. Geldings with objectionable masculine behavior, and some geldings are neither produced nor released by the epididymis, and therefore, the presence or absence of epididymal tissue should not influence masculine behavior.\textsuperscript{192} Because masculine behavior of a false rig cannot be justly attributed to retention of epididymal tissue, there is no such thing as a proud cut horse.\textsuperscript{195}

Masculine behavior of a false rig has also been attributed to production of testosterone by the adrenal cortex.\textsuperscript{120} The circulating concentration of luteinizing hormone is increased after castration in response to the falling concentration of testosterone, and the rise in luteinizing hormone concentration may produce some adrenal hypertrophy. False rigs, however, have no higher concentration of testosterone or dihydrotestosterone in serum than do normal, quiet geldings, and the presence of significant concentration of any other androgen is unlikely.\textsuperscript{195} Moreover, administering hCG to false rigs produces no discernable rise in concentration of testosterone in serum.

Heterotopic testicular tissue has been incriminated as a cause of continued masculine behavior after castration.\textsuperscript{196} Failure of embryonic primordial germ cells to migrate caudally and dispersion of the cells of the embryonic germinal epithelium from trauma have been theorized as causes of transplantation of testicular tissue throughout the peritoneal cavity of pigs.\textsuperscript{196} The occurrence of heterotopic testicular tissue in horses, however, has not been reported. Administering hCG to a horse with heterotopic testicular tissue would probably produce a rise in concentration of testosterone in the serum.

Objectionable masculine behavior after castration is most likely innate and not caused by extragonadal production of testosterone.\textsuperscript{195,197} Masculine behavior of false rigs is probably part of the normal social interaction between horses.\textsuperscript{195} About 20% to 30% of castrated horses can be expected to display stallion-like sexual interest in mares and aggression toward other horses, and about 5% can be expected to display stallion-like aggression toward people.\textsuperscript{197} Because the prevalence of masculine behavior of horses castrated as juveniles is similar to that of horses castrated as adults, castration before puberty is no more effective in preventing objectionable behavior than castration after puberty. These percentages should be considered the normal prevalence of masculine behavior in geldings.

Amputating the stumps of the spermatic cords was reported to abolish objectionable masculine behavior in 75% of 18 false rigs,\textsuperscript{198} but no satisfactory rationale was offered to account for the success of this procedure. Because spermatic cords contain no Leydig cells and are incapable of producing androgens, the efficacy of shortening cords to eliminate libido seems doubtful. Limiting social interaction with other horses or imposing stricter discipline may be more successful in eliminating or diminishing undesirable masculine behavior.\textsuperscript{192}

**Incomplete Cryptorchid Castration**
The tail of the epididymis of the partial abdominal cryptorchid lies within the inguinal canal, enclosed in a well-developed vaginal process. Excessive length of the proper ligament of the testis and body of the epididymis may allow the tail of the epididymis to descend through the inguinal canal. A surgeon unfamiliar with testicular anatomy and the mechanism of testicular descent may amputate the tail of...
the epididymis after mistaking it for a hypoplastic inguinal
testis (Fig. 65-27). The horse naturally continues to display
objectionable, stallion-like behavior.

The vaginal tunica should be opened before removing a
structure presumed to be an inguinal testis to ensure that a
testis, and not just the epididymis, is contained within. An
hCG-stimulation test differentiates a horse with testicular
tissue from a false rig. Locating both the end of the epi-
didymis and the stump of the ductus deferens in the inguinal
canal at surgery identifies a horse as a partial abdominal
cryptorchid whose epididymis has been partially resected.13

810  REPRODUCTIVE SYSTEM

ANATOMY AND PHYSIOLOGY
Penis
The penis is the male organ of copulation and is composed of erectile tissue that encases the extrapelvic portion of the urethra (Fig. 66-1). The penis of the horse is musculo-cavernous and can be divided into three parts: the root, the body or shaft, and the glans penis. The penis originates caudally at the root, which is fixed to the lateral aspects of the ischial arch by two crura (leg-like parts) that converge to form the shaft of the penis. The shaft constitutes the major portion of the penis and begins at the junction of the crura. It is attached caudally to the symphysis ischii of the pelvis by two short suspensory ligaments that merge with the origin of the gracilis muscles (Fig. 66-2). The glans penis is the conical enlargement that caps the shaft. The urethra passes over the ischial arch between the crura and curves cranio-ventrally to become incorporated within erectile tissue of the penis.

The mobile shaft and glans penis extend cranioventrally to the umbilical region of the abdominal wall. The body is cylindrical but compressed laterally. When quiescent, the penis is soft, compressible, and about 50 cm long. Fifteen to 20 cm lie free in the prepuce. When maximally erect, the penis is up to three times longer than when it is in a quiescent state.

Erectile Bodies
Two cavernous spaces make up the majority of the penile shaft: the dorsally located corpus cavernosum penis (CCP), which is responsible for erection, and the ventrally located corpus spongiosum penis (CSP), formerly termed the corpus cavernosum urethrae (Fig. 66-3). The CCP originates below the ischial arch at the union of the crura, which attach to the ischial arch, and makes up the bulk of the shaft. It ends distally in one long central and two blunt ventrolateral projections (Fig. 66-4). Along the ventral surface of the CCP runs the urethral groove or urethral sulcus.

The CSP lies in the urethral groove of the CCP and surrounds the urethra (see Fig. 66-3). The bulb of the penis is the proximal enlargement of the CSP. At its distal termination, the CSP expands into the glans penis, which caps the central projection of the CCP (see Fig. 66-4). The tunica albuginea of the glans is thinner than that of the rest of the penis, making it softer in the erect state than the CCP.

A long dorsal process of the glans penis extends 10 cm proximally on the dorsum of the CCP. The circular edge of the glans penis is termed the corona glandis, and the collum glandis represents the constriction behind it. The convex, cranial surface of the glans contains a deep...
depression, the fossa glandis, into which the urethra protrudes 1.5 to 3.0 cm as a free tube surrounded only by thin integument\(^1\) (Fig. 66-5). This tubular protrusion of the urethra is termed the urethral process. A dorsal diverticulum of the fossa glandis, the urethral sinus, is often filled with smegma, a caseous mass of sebaceous matter and epithelial debris. A collection of hardened smegma in the urethral sinus is termed a bean. Large beans have been purported to interfere with urination. Two ventrolateral recesses also project from the fossa glandis.\(^4\) The fossa glandis and its recesses can harbor bacteria capable of producing venereal disease.\(^7\)

The erectile bodies are surrounded by the thick, fibro-elastic tunica albuginea, which sends fibrous trabeculae inward to form the supporting framework of the cavernous spaces.\(^1,2,6\) The CSP has thinner trabeculae with larger,
veinlike cavernous spaces than seen in the CCP. The tunica albuginea of the CSP is thin and elastic and merges distally with the integument of the glans. The cavernous spaces are lined with endothelial cells and longitudinally oriented bundles of smooth muscle. Tonus of these muscular trabeculae and the retractor penis muscles maintains the nonerect penis within the prepuce. Decrease in tonus, as during micturition, causes the nonerect penis to protrude from the prepuce.

**Mechanism of Erection**

Penile erection is a neurovascular phenomenon, and the primary hemodynamic event leading to erection is increased arterial flow to the cavernous spaces. Sexual excitement stimulates parasympathetic outflow from the sacral portion of the spinal cord and results in dilation and straightening of the helicine arteries (coiled branches of the deep artery of the penis) and relaxation of the sinusoidal smooth muscles, enabling blood to pass into the sinusoidal spaces. Engorgement of the cavernous spaces, which is controlled and finally stopped by the unyielding tunica albuginea and trabeculae, lengthens and stiffens the penis.

Obstruction of venous return from the CCP appears to be important during erection in the stallion. Circulation to and from the CCP passes between the ischium and the ischiocavernosus muscles. Contraction of the ischiocavernosus muscles from stimulation of the pudendal nerves occludes arterial and venous flow against the ischium, making the CCP a closed system during peak erection. Compression of the crura by the ischiocavernosus muscles forces blood into the CCP to produce high pressures. In one study, the mean pressure within the quiescent CCP measured 13 mm Hg but it rose to 107 mm Hg during sexual arousal, and finally to 6530 mm Hg during coitus. Anesthesia of the ischiocavernosus muscles caused diminution of erection by reducing the peak pressure in the CCP to a value close to that of the systemic blood pressure.

During coitus, increased arterial blood flow into the CSP and contraction of the bulbo cavernosus muscles lead to increased pressure within the CSP and considerable distention of the glans penis. The glans penis is greatly distensible and may become so large before coitus that the stallion is unable to accomplish intromission. In one study, mean pressure within the CSP was 17 mm Hg during the quiescent state, 76 mm Hg on arousal, and finally, 994 mm Hg during coitus. Contractions of the bulbospongious muscles were likely responsible for the high pressure, because anesthesia of these muscles greatly reduced pressure in the CSP during coitus. The CSP remains an open system after coitus because vessels entering the bulb of the penis do not pass between an osseous structure and the bulbospongiosus because vessels entering the bulb of the penis do not pass through. Rhythmic contractions of the bulbospongiosus muscle during ejaculation force blood from the bulb, causing a pressure wave to be sent down the CSP to forcefully expel semen from the urethra.

**Blood Vessels, Nerves, and Lymphatics**

Arteries supplying the penis include the terminal branches of the internal pudendal, obturator, and external pudendal arteries. The external pudendal artery supplies the cranial artery of the penis, a major source of blood for erectile tissue. It supplies a branch to the scrotum and continues as the caudal superficial epigastric artery, which provides branches to the prepuce. The deep arteries of the penis originate from the obturator arteries and supply the CCP. The internal pudendal artery supplies the pelvic portion of the urethra and terminates in the CSP as the artery of the bulbo cavernosus muscle, which supplies the CCP. Blood flows from the penis through a venous plexus on the dorsum and sides of the penis. The venous plexus is emptied by the external pudendal and obturator veins; blood is carried from the root of the penis through the dorsal veins.

Nervous supply to the penis is primarily via the pudendal nerves and the pelvic plexus of the sympathetic nervous system. The pudendal nerves branch into the dorsal nerves of the penis, and the sympathetic fibers supply the smooth muscle of the vessels and the erectile tissue. The deep perineal and caudal rectal nerves supply the bulbospongiosus,
ischiocavernosus, and retractor penis muscles. Efferent lymphatics of the penis carry lymph to the superficial and deep inguinal lymph nodes.

**Accessory Genital Glands**

The accessory genital glands of the horse are the paired seminal vesicles, the prostate, the paired bulbourethral glands, and the paired ampullae of the ductus deferens (Fig. 66-6). The accessory genital glands are fully developed in the sexually mature stallion but resume their juvenile size in the gelding. The ducts of these glands empty into the pelvic urethra and provide the major portion of the ejaculate. Secretions from the seminal vesicles are the last to enter the urethra. Seminal vesiculitis, a rare but important problem in stallions, may be associated with infertility. Surgical removal of chronically infected vesicles has been described.

The prostate is a nodular, bilobed gland that lies dorsal to the neck of the bladder. The prostate of a stallion can, with some difficulty, be palpated per rectum, especially if the horse is sexually aroused. Each lobe is 5 to 9 cm long, 3 to 6 cm wide, and about 1 cm thick; the lobes are connected across the midline by a 3-cm-long isthmus. Prostatic secretion from each lobe is carried through 15 to 20 prostatic ducts, which open into the urethra through small, slit-like openings located lateral to the colliculus seminalis. The prostate produces a watery, alkaline secretion that neutralizes the acidity of fluid entering the urethra from the ductus deferens.

The two bulbourethral (or Cowper’s) glands are situated on the dorsolateral surface of the urethra at the ischial arch, 2 to 3 cm caudal to the prostate. Each is covered by a bulboglandularis muscle. The bulbourethral glands of the stallion are 4 to 5 cm long and 2.5 cm wide and are difficult to palpate per rectum. Six to eight excretory ducts from each gland open in two longitudinal rows of small papillae on the dorsal surface of the pelvic urethra caudal to the openings of the prostatic ducts. The bulbourethral glands produce an alkaline, mucinous secretion that clears the urethra of urine prior to ejaculation and lubricates the urethra for the passage of seminal fluid.

**Prepuce**

The prepuce, or sheath, is a voluminous, folded "sleeve" of integument covering the mobile portion of the quiescent penis. The prepuce consists of the haired external lamina, which is continuous with the skin of the abdominal wall, and an internal lamina, which is in contact with the penis (see Fig. 66-5). The external lamina extends cranially from the scrotum to within 5 to 8 cm of the umbilicus and is continuous with the internal lamina at the opening of the prepuce, the preputial orifice (see Fig. 66-1). Close to the cranial extent of the external lamina are two rudimentary teats. The preputial raphe, a cranial continuation of the scrotal raphe, divides the external lamina sagittally on its ventral midline. The prepuce is supported by an elastic suspensory ligament that lies within the external lamina and is derived from the abdominal tunic. When the horse trots or canters, movement of the penis within the prepuce often creates a sucking noise.

The prepuce of the horse differs from that of other species in that it is formed by a double fold of preputial skin, one inside the other. When the penis is retracted, the internal lamina doubles on itself to form a cylindrical internal fold, the plica preputialis or preputial fold. The preputial cavity is thus divided into external and internal cavities, of which the external is the more spacious. The opening of the plica preputialis is termed the preputial ring. When the plica preputialis unfolds during erection, the preputial ring can be recognized as a thickened band on the extended penis.

The penis is not free in the preputial cavity at birth, because epithelium of the internal lamina of the prepuce and epithelium of the free part of the penis are fused into a
single lamina. The lamina is split into external and internal laminae by a cytolytic process that forms vesicles that coalesce to form the preputial cavity.18,19 Separation of the internal and external laminae occurs in the first month after birth and is controlled by androgens.

**DIAGNOSTIC PROCEDURES**

**History**

Most preputial and penile abnormalities are easily diagnosed from the horse's history and during physical examination, and further studies are not required. History pertaining to problems of the penis and prepuce may include such information as copulatory performance, drug therapy, behavioral changes, conception rates, duration of disability, and previous injuries, illnesses, or urogenital surgery.

**Clinical Examination**

**Urination**

Physical examination of a horse with a penile or preputial disorder should include observation of urination. The horse can sometimes be stimulated to urinate by placing it in a freshly bedded stall; shaking the bedding while whistling may increase the horse's urge to urinate. If this technique fails, intravenously administered furosemide generally results in urination within 15 minutes. If the horse makes painful and unsuccessful attempts to urinate, urethral obstruction should be suspected, and the bladder should be palpated per rectum. If the bladder is distended, it should be catheterized to relieve its distention and to determine the location of urethral obstruction. A large accumulation of hardened smegma within the fossa glandis can produce stranguria by distorting the urethral process, but this accumulation is readily identified and easily removed.

**Erection and Ejaculation**

A breeding stallion that is experiencing difficulty with erection or ejaculation should be observed servicing a mare. Inability of a sexually excited stallion to achieve erection could be caused by a vascular shunt from the CCP to a vessel outside the tunica albuginea, or by fibrosis of cavernous tissue from an unresolved episode of priapism. Shunts between the CCP and one or more dorsal veins of the penis could result from a congenital anomaly or from laceration or rupture of the tunica albuginea. Damage to the CCP caused by priapism (persistent erection without sexual excitement) can be assessed by palpating the cavernous tissue. Fibrous, noncompliant cavernous tissue indicates that the CCP has been permanently damaged. A stallion that is reluctant to ejaculate or displays pain during ejaculation may suffer from urethritis or seminal vesiculitis. If so, semen should be examined for the presence of blood, and the urethra should be endoscopically inspected for evidence of seminal vesiculitis or a urethral abnormality.

**Palpation**

The penis can be palpated as it lies retracted in the prepuce by inserting a gloved and lubricated hand through the preputial orifice and preputial ring. This may be the only method of physically evaluating the penis and internal preputial lamina of a horse with phimosis (an inability to protrude the penis from the prepuce because of a stricture of the preputial orifice or preputial ring). The external and internal preputial cavities, preputial ring, and free part of the penis, including the urethral sinus and process, can be evaluated by palpation. Beans within the urethral sinus can usually be palpated by compressing the tip of the penis. Dense, brown-black, greasy smegma is normally encountered at the preputial fornx.

**Visual Inspection**

To ascertain the exact nature and extent of penile or preputial abnormalities, visual inspection of the horse's penis and internal preputial lamina is usually necessary. The stallion's penis can be protruded by administering xylazine HCl or preferably by stimulating sexual arousal. Administration of phenothiazine-derivative tranquilizers to stallions should be avoided because of association of these tranquilizers with penile paralysis and priapism. The gelding's penis can be protruded by administering a tranquilizer or sedative or by placing a loop of gauze behind the corona glandis and with steady traction overcoming the pull of the retractor penis muscles. Producing penile protrusion by chemical means is preferable to pulling the penis from the prepuce, because traction on the penis is resented by the horse and could damage the penis.

The penis can be desensitized and extruded by anesthetizing the pudendal nerves at the level of the ischial arch.20 The point of injection is 2 cm dorsal to the ischial arch and an equal distance lateral to the anus. The needle is inserted at an angle until its point contacts the ischial arch on the midline where the pudendal nerves course around the ischium. The penis usually protrudes within 5 minutes after deposition of 3 to 5 mL of a local anesthetic agent adjacent to each nerve. Unless prolonged penile desensitization is required, a short-acting local anesthetic, such as lidocaine HCl, should be used to avoid prolonged penile protrusion. Desensitization and extrusion of the penis and internal lamina of the prepuce by anesthetizing the right and left pudendal nerves where they are embedded in the sacrotuberous ligament is described, but this pudendal nerve block is difficult.20

The urethral process and fossa glandis should be inspected for lesions of cutaneous habronemiasis. With the penis extended, the entire internal preputial lamina is visible and can be evaluated for wounds, scars, hematomas, neoplasia, and granulomas. Penile and preputial wounds should be closely examined to determine if they penetrate the tunica albuginea or invade the urethra. Leakage of urine from a traumatized area may be noted, especially when the horse urinates. A hematoma should be differentiated from an abscess. Physical findings of hematoma include penile swelling and ecchymosis, particularly noticeable in non-pigmented areas. Aspiration of a hematoma confirms the diagnosis. Examination of a horse with paraphimosis (an inability to retract the protruded penis into the prepuce) should include an evaluation of penile sensory innervation, because protrusion accompanied by penile paralysis may be permanent.
If preputial or penile neoplasia is suspected, the entire external genitalia should be examined meticulously for other primary lesions, and the inguinal regions should be palpated to detect enlarged lymph nodes. Superficial inguinal lymph nodes may enlarge initially from inflammation but later from malignant infiltration. Lymph nodes adhered to overlying skin or with fistulous tracts have most likely been infiltrated by malignant emboli. Metastases to internal lymph nodes may be detected by palpation per rectum. Recognition of carcinoma of the external genitalia should lead to examination of other structures commonly affected by carcinoma, such as the third eyelids and the perineum.

**Other Diagnostic Procedures**

**Endoscopy**

Endoscopy may be useful for identifying the source of hemorrhage noted to occur during urination or ejaculation. Endoscopy of the urethra and bladder is performed with the horse standing and sedated using a sterile, 100-cm (or longer), flexible endoscope with a diameter no larger than 12 mm. The vasculature and cavernosal spaces surrounding the urethra are prominent, especially in the proximal portion of the urethra, and should not be mistakenly interpreted as inflammation. The lumen of the seminal vesicles can be examined for evidence of infection by passing the insertion tube of a small-diameter endoscope into the ducts at the colliculus seminalis.22

**Ultrasonography**

Ultrasonography can be used to assess the physical status of cavernous tissue and to identify urethral lesions, such as calculi or stenosing scars. Ultrasonographic examination of a penile hematoma may identify a rupture of the tunica albuginea. Abnormality of an accessory sex gland can sometimes be detected using transrectal ultrasonography.14 The glands can be more readily identified if the stallion has been sexually aroused before ultrasonographic examination.

**Cavernosography**

Cavernosography may be useful for determining the cause of persistent impotence. Contrast medium (100 to 200 mL of iohexol, a 24% water-soluble, organic iodine radiographic contrast medium) is injected into the CCP, and serial radiographs of the penis are obtained. If shunts are present, contrast medium appears in the nutrient vessels of the penis and prepuce. If trabeculae are damaged, the sinusoidal spaces fill incompletely with contrast medium. Cavernosography also may be useful in identifying a rupture or laceration of the tunica albuginea of the CCP.

**Miscellaneous Diagnostic Procedures**

Urethral and ureteral catheterization may be useful for determining the source of hemorrhage observed to occur during urination or ejaculation or to obtain fluid expressed from the seminal vesicles for cytologic examination and culture.25 Cytologic or histologic evaluation of penile and preputial lesions may be necessary to distinguish between various diseases, such as cutaneous habronemiasis and squamous cell carcinoma.

**PENILE AND PREPUTIAL DISORDERS**

**Penile and Preputial Injuries**

**Etiology**

Horses can lacerate their penis while jumping barriers or attempting to breed a mare over a fence, by falling on sharp objects, or during coitus from the mare’s tail hairs or a loosely tied “breeding stitch.” Stallion rings that are too small or improperly cleaned may cause erosions of the shaft.23 Penile hematomas are usually caused by trauma to the erect penis and can occur when stallions are pastured with other horses or permitted to breed improperly restrained mares. Severe bending of the penile shaft during coitus or semen collection may cause tearing of a corporeal body or subfascial vessels on the surface of the penis.

Penile lacerations or erosions are usually superficial, but lacerations into the cavernous tissue and urethra have been reported.24-28 A tear in the urethral sinus leading directly into the CSP caused severe penile hemorrhage in a stallion during coitus,25 and improper castration of two horses caused urethral damage and necrosis of tissue at the scrotum from escape of urine.26,27

Hematomas usually arise from rupture of the extensive vascular plexus located subfascially on the surface of the penis,29 but occasionally, a hematoma may originate from a torn corporeal body.30 Rupture of the CCP is sometimes referred to as fracture of the penis. Rupture of the bulb of the penis, presumably from a blow, eventually led to the death of a stallion by causing urethral stenosis and subsequent rupture of the bladder.31 A hematoma confined within the intact tunica albuginea of the CCP, apparently caused by a breeding accident, resulted in deviation of a stallion’s penis during erection, presumably from disruption of blood flow through the cavernous structure.32 Aspiration of the hematoma, using ultrasonographic guidance, resulted in straightening of the penis.

**Pathophysiology**

Unsutured preputial lacerations inevitably become infected, and migration of infection through the loose preputial connective tissue results in cellulitis and generalized swelling. If cellulitis and swelling become severe, the penis and internal lamina of the prepuce protrude through the preputial orifice. Superficial wounds, if properly treated, heal without complication, but large unattended wounds that heal by cicatrization may restrict action of the prepucce. An unsutured wound into cavernous tissue may lead to impotence caused by creation of a shunt between the cavernous tissue and the superficial penile vasculature. Although longitudinal urethral lacerations generally heal without stricture when left to heal by secondary intention, unsutured, transecting urethral lacerations usually heal with obstructing stenosis. An improperly attended urethral injury could result in a cutaneous-urethral or cavernosourethral fistula.

Rupture of superficial penile vessels or corporeal bodies causes extravasation of blood into the loose preputial fascia. Extreme preputial swelling may occur within minutes of...
injury and may prevent the horse from retracting its penis into the preputial cavity. The penis may rapidly enlarge to several times its normal size. The hematoma may interfere with venous and lymphatic drainage by impinging on undamaged veins and lymphatic vessels, thus exacerbating the swelling or the hematoma may interfere with urination by impinging on the urethra.

**Treatment**

**OPEN WOUNDS**

To avoid infection, fresh penile and preputial wounds should be débrided and sutured. Sutures can be either absorbable or nonabsorbable but should be soft and non-irritating. Infected wounds should be frequently cleansed with a mild antiseptic solution several times daily and covered with an antimicrobial ointment. If the urethra is completely disrupted, it should be reaposed with absorbable suture; stenting the urethral lumen with a male urinary catheter during surgery simplifies the anastomosis. Stenosis of the urethra caused by cicatrix formation after injury can sometimes be relieved by transendoscopic laser ablation. Often, penile amputation is the most expedient means of treating complete urethral disruption accompanied by severe trauma of surrounding tissue, especially if the injured horse is a gelding.

**HEMATOMAS**

Treatment of a horse with a penile hematoma should be instituted immediately after injury and aimed at decreasing hemorrhage. Compressing the penis and internal lamina of the prepuce with a pneumatic bandage or tight wrap may relieve edema and minimize hemorrhage. To compress the penis and prepuce, the horse is anesthetized, and starting at the distal end of the penis, the penis and internal lamina of the prepuce are wrapped snugly from the glans to the preputial orifice with an elastic bandage. The wrapped penis and prepuce and the preputial orifice are massaged until the wrap loosens from the decrease in size of the penis and prepuce. The process is repeated until maximal decrease in size is achieved. The penis and internal lamina of the prepuce should then be supported against the abdomen or within the external prepuce to diminish hemorrhage and edema. Hydrotherapy with cold water may hasten vasoconstriction. If the hematoma continues to expand despite treatment, the area of the hematoma should be examined ultrasonographically for evidence of a rent in the tunica albuginea, or surgically explored. Failure to repair a rupture of the tunica albuginea could result in formation of a shunt between the damaged erectile body and the dorsal veins of the penis.

**Aftercare**

To avoid erection and more hemorrhage, a horse with a penile or preputial injury should not be subjected to sexual stimuli. Because exercise may exacerbate hemorrhage, the horse should initially be closely confined. After 5 or 6 days, when hemostasis is ensured, the horse should be lightly exercised to decrease the edema. Hot packs applied to the penis at this time stimulate vasodilatation and thus resorption of the hematoma.

**Paraphimosis**

**Etiology**

Paraphimosis, or the inability of the horse to retract its protruded penis into the prepuce, occurs most frequently from preputial edema caused by genital trauma, such as preputial laceration, penile hematoma, or castration. Paraphimosis may be a manifestation of disease characterized by extensive edema, such as dourine and purpura hemorrhagica, or it may be caused by damage to penile innervation. Penile denervation has been associated with spinal disease, trauma, and infectious diseases, such as equine herpes virus I and rabies. Paralysis associated with priapism and debilitation has been reported (Fig. 66-7). Penile paralysis has followed administration of
phenothiazine-derivative tranquilizers, most notably propiomazine (formerly termed propiomazine).39,40

Pathophysiology
Tonus of the retractor penis muscles and the smooth muscle of the cavernous spaces normally maintains the penis within the prepuce.37 With penile or preputial injury, edema develops in loose connective tissue between the penis and the internal lamina of the prepuce, and the weight of edema causes muscular fatigue, followed by protrusion of the penis and internal preputial lamina from the preputial cavity. The relationship between debilitation and penile paralysis is obscure, but general debilitation may cause loss of muscular tonus, allowing the penis to protrude and the pudendal nerves to become contused or stretched at the ischial arch.37,41,42 Penile paralysis occurring after administration of a phenothiazine-derivative tranquilizer may likewise be caused by mechanical damage to the pudendal nerves from prolonged penile protrusion and not from direct damage to penile innervation by the tranquilizer, as suggested by one investigator.39 Motor innervation of the retractor penis muscles is probably supplied solely by α-adrenergic fibers, and phenothiazine-derivative tranquilizers block these α-adrenergic fibers.1 The retractor penis muscles can, however, be transected without causing the penis to protrude. Tranquilization may also block sympathetic impulses to the smooth muscle of the cavernous tissue, allowing the sinusoidal spaces to fill with blood and the penis to drop from the preputial cavity.36

Prolonged protrusion itself produces edema of the penis and prepuce by impairing venous and lymphatic drainage. As the penis and internal preputial lamina swell from edema, the preputial ring becomes a constricting cuff that compounds swelling distally. After several days, fluid begins to seep diffusely through the penile and preputial epithelium. Edema increases fragility of tissues, and because the exposed penis is subjected to trauma and effects of temperature, the penile and preputial epithelia soon become extensively excoriated.

Bacterial invasion of excoriated epithelium causes inflammation of the penis and prepuce, or balanoposthitis, and bacterial migration through the loose preputial connective tissue causes cellulitis. Eventual invasion of edematous and inflamed tissue by fibroblasts results in fibrosis of the penile integument and fascia, causing permanent impairment of the normal telescoping action of the prepuce.37 The pendulous weight of the penis may eventually damage the pudendal nerves.40,41

The protruded penis becomes curved with the glans penis pointing caudoventrally. Urination is usually unimpeded.40 Paralysis is usually accompanied by loss of erectile function, but ejaculatory capability is often still preserved.23

Treatment
Treatment of a horse affected with paraphimosis should be directed toward controlling edema and preventing further trauma. To preserve normal venous and lymphatic drainage and to protect against injury, the penis should be retained within the external preputial lamina. The penis can be temporarily retained with sutures or towel clamps placed across either the preputial orifice or preputial ring, but these devices should not be relied on for more than several days, because they damage the prepuce. Prolonged, atraumatic support can be provided by a nylon net or hosiery suspended at the preputial orifice by a crupper and surcingle made of rubber tubing (Fig. 66-8).

If the protruded penis is too edematous to be replaced within the external preputial lamina, it should be compressed against the abdomen with a bandage until edema subsides. A pneumatic bandage or a tight bandage applied directly to the penis may also be effective in reducing edema. Applying a nonirritating, hydrophilic agent, such as glycerin, or sulfa-urea to the penis may increase the effectiveness of the compressive bandage. Massaging the penis between bandage changes is helpful for dissipating edema. Applying an antimicrobial ointment to the penis prevents epithelial maceration and infection, and a systemically administered nonsteroidal anti-inflammatory drug reduces inflammation. The horse should be lightly exercised to reduce edema.

If the relatively inelastic preputial ring prevents penile retraction or impedes venous and lymphatic drainage, a
Preputiotomy can be performed. The preputial ring is severed with a longitudinal incision after administration of local or general anesthesia, and the incision is allowed to heal by secondary intention. With prompt treatment, paraphimosis resulting from acute trauma usually resolves within several days. Even after initial swelling and inflammation subside, preputial cicatrization may restrict normal telescoping action of the prepuce. Excision of restrictive cicatricial tissue by segmental posthetomy (reefing) may be necessary to restore normal preputial function (see “General Surgical Procedures,” p. 827). Horses with chronic paraphimosis accompanied by penile paralysis or generalized preputial fibrosis are unlikely to regain the ability to retract the penis. Stallions with penile paralysis generally retain their libido but are unable to achieve erection. For some stallions, however, ejaculation may still be possible. Penile paralysis need not necessarily end a stallion’s breeding career, if the stallion can be trained to ejaculate into an artificial vagina (provided that the horse’s breed registry permits artificial insemination). The horse can be salvaged for purposes other than breeding by permanently retracting its penis into the preputial cavity or by amputating its penis (see “General Surgical Procedures,” p. 827).

Phimosis

Etiology

Phimosis refers to the inability of the horse to protrude its penis from the prepuce because of a congenital or acquired stricture of the preputial orifice or preputial ring. Discounting the normal fusion of the internal lamina of the prepuce to the free part of the penis present during the first month after birth, congenital phimosis rarely, if ever, occurs in horses.

Acquired phimosis can result from tumors or cicatrizing lesions at the preputial orifice or preputial ring (Fig. 66-9) or from impairment of the normal telescoping action of the prepuce. When the horse cannot protrude its penis, urine enters the preputial cavity and produces mucosal inflammation that may eventually lead to more cicatrization and occlusion of the preputial orifice or preputial ring. An unusual cause of phimosis occurred when a gelding’s penis became entrapped in a rent in the suspensory ligament of the prepuce. The ligament had apparently been torn when the horse was castrated.

Treatment

If phimosis is caused by constriction of the preputial orifice, a wedge of external preputial lamina based toward the preputial orifice is removed. The internal and external preputial laminae are joined with a row of closely spaced, interrupted sutures. If phimosis is caused by constriction of the preputial ring, a similar wedge can be removed from the internal preputial fold, and after the penis is exposed, the constricting cicatrix can be removed by segmental posthetomy (reefing) (see “General Surgical Procedures,” later). Phimosis caused by rupture of the suspensory ligament of the prepuce is corrected by suturing the torn ligament.

Priapism

Priapism, or persistent erection without sexual excitement, occurs when the erect penis fails to detumesce. The condition derives its name from the Greek god Priapus, symbol of fertility, but a frequent outcome of the condition in all species in which it occurs is infertility resulting from impotency.

Etiologic Factors

Etiologic factors in the development of priapism in men include hematologic diseases that cause vascular sludging, such as sickle cell anemia and leukemia; administration of antihypertensive or antidepressant drugs, especially when combined with alcohol; perineal trauma; spinal cord injury; and inflammatory disorders of the urogenital tract. Priapism of horses usually occurs after administration of a phenothiazine-derivative tranquilizer, usually acetylpromazine. Phenothiazine-derivative tranquilizers may cause failure of detumescence by blocking α-adrenergic impulses that mediate detumescence. Other, less commonly reported causes of priapism of horses include general anesthesia, nematodiasis of the spinal cord, and neoplasia of the pelvic canal. Priapism occurs in both stallions and geldings, but stallions are more commonly affected, perhaps because of a direct influence of androgens on development of the condition, or perhaps because stallions develop erections more frequently.

Pathophysiology

During normal erection, the rate of flow of blood into the CCP equals the rate of flow of blood from the structure. The precise mechanisms by which priapism occurs are unknown, but basically, priapism is a result of a disturbance of either the arterial inflow or the venous outflow to the CCP, causing the erect penis to fail to detumesce.
in men is classified as being either high flow or low flow. High-flow priapism occurs when arterial blood flow to the cavernosal tissue is increased, usually as a result of a traumatologically induced arteriocavernosal shunt, and venous drainage cannot compensate for this increase. Low-flow priapism occurs when the neural impulses that mediate detumescence are altered or when vascular or hematologic alterations mechanically interfere with venous drainage. High-flow priapism in men almost always results from trauma to the perineum or penis. Low-flow priapism occurs in men much more commonly than does high-flow priapism, and it is the only type of priapism reported to occur in horses.

Low-flow priapism, regardless of its etiology, is characterized by stasis of blood within the CCP (Fig. 66-10). Blood aspirated from the CCP of men affected with low-flow priapism has a low pH (typically, less than 7.25), a low partial pressure of O₂ (typically, less than 30 mm Hg), and a high partial pressure of CO₂ (typically, greater than 60 mm Hg). High partial pressure of CO₂ caused by vascular stasis, causes erythrocytes to sickle and causes endothelial damage to the vessels and trabeculae in the CCP. The sickled erythrocytes occlude the venous outflow from the CCP, eventually irreversibly. Endothelial damage and occlusion cause trabecular edema, which eventually progresses to fibrosis, thereby decreasing the size of the sinusoidal spaces in the CCP and the capacity of the CCP to expand during erection. Arterial flow to the CCP remains patent during early stages of priapism, but ultimately, it too becomes occluded permanently by clots, edema, or fibrosis. Protracted erection in the horse may also damage the pudendal nerves, presumably from tension on the nerves or from compression of the nerves against the ischium, causing paralysis of the penis. The end result of unresolved priapism in the horse is impotence caused by loss of both erectile function and sensitivity of the glans and shaft of the penis.

Clinical Signs

A horse suffering from priapism may not have a full erection, causing the penis to appear to be paralyzed or merely protruded rather than erect. Turgidity of the CCP can be detected when the penis is palpated, however, and the engorged penis cannot be reduced manually into the prepucce. Unless properly cared for, the penis and the internal lamina of the prepucce become edematous soon after the onset of priapism. Although uncommon, dysuria may be a feature of the condition. The CCP of a horse chronically affected by priapism feels fibrous, and during ultrasonographic examination, it appears to be densely echogenic. A chronically affected horse may not respond when a noxious stimulus is applied to the distal portion of the penis or internal lamina of the prepucce.

Treatment

MEDICAL

Horses with priapism have been treated by massaging the penis, by applying an emollient dressing to the penis, and by compressing the penis against the body wall with a sling.

These treatments, although important in preventing preputial edema and damage to the penis and preputial integument, have no effect on re-establishing normal circulation in the erectile tissue of the CCP. To re-establish normal venous drainage impaired by drugs that cause α-adrenergic blockade, such as acetylpromazine, affected horses have been treated by administration of benztpoline mesylate. Benztpoline mesylate is a synthetic drug created by combining the active portions of atropine and diphenhydramine. This drug is most successful in resolving priapism if treatment is initiated soon after the onset of priapism. The effects of the drug on horses affected with priapism are attributed to its anticholinergic effects. The usual dose for a horse of average size is 8 mg, administered by slow intravenous injection. Side effects seen at higher dosages could include paralytic ileus, impaction, dysuria, and muscular weakness.

Alpha-adrenergic agents, such as adrenalin and phenylephrine, are often injected into the CCP of men in the early stages of priapism to achieve detumescence by promoting contractility of cavernous and arterial smooth muscle. Instillation of 10 mg of phenylephrine diluted in 10 mL physiologic saline solution directly into the erect CCP is sometimes effective in resolving priapism of horses, provided that treatment is initiated soon after onset of priapism. Phenylephrine can be injected safely into the cavernous tissue of men every 15 minutes until detumescence occurs, and the same is probably true for horses. Horses chronically affected by priapism experience only temporary detumescence after this treatment.

IRRIGATION OF THE CORPUS CAVERNOSUM PENIS

A horse that does not respond within a few hours to cholinergic blockade or to three or more intracavernosal injections of an α-adrenergic agent, such as phenylephrine, should be treated by irrigation of its CCP with heparinized, physiologic saline solution (PSS). Irrigation of the CCP not only removes sickled erythrocytes, it also improves the acidotic environment within the CCP. The CCP can be irrigated with the horse standing, but the procedure is most easily accomplished with the horse anesthetized and in dorsal recumbency. After preparing the penis and perineal area for aseptic surgery, PSS containing 10 IU heparin/mL is introduced into the CCP under pressure through a large-bore needle (e.g., a
12-gauge needle) inserted into the turgid CCP just proximal to the glans penis. The PSS, along with the stagnant blood, is exited 10 to 15 cm caudal to the scrotum, either through one or two large-bore needles inserted into the CCP or through a stab incision into the CCP. The CCP is irrigated until fresh blood appears in the efflux. Failure of arterial blood to appear in the efflux after stagnant blood has been evacuated indicates that the arteriolar supply to the CCP is permanently damaged and that the horse is likely to be impotent. The stab incision in the tunica albuginea of the CCP is sutured after irrigation is complete.

**CREATION OF A SHUNT**

Erection recurs after irrigation if venous outflow remains occluded, provided that arteriolar inflow vessels remain patent. If erection fails to resolve after several irrigations of the CCP, blood trapped in the CCP should be removed by creating a shunt between the CCP and the corpus spongiosum penis (CSP). The CSP offers a convenient exit for blood trapped in the CCP, because in contrast to the CCP, the CSP does not act as a closed system during erection. Shunting should be performed before the cavernous tissue or the pudendal nerves become irreversibly damaged, but the time at which damage to the cavernosal tissue becomes irreversible after the onset of priapism has not been determined for horses.

The shunt is probably best performed in the perineal region of the horse. It could be created further distally, but creating it in the perineal region allows a more thorough evacuation of the stagnant blood by irrigation and provides drainage of blood from a greater length of the CCP. Because the CSP is thickest in the perineal region, the urethra is less likely to be perforated during the procedure. To create the shunt, the horse is anesthetized and positioned in dorsal recumbency. The penis and inguinal and perineal regions are prepared for aseptic surgery, and a stallion catheter is inserted into the urethra. A 15-cm incision is created along the perineal raphe, about 4 to 8 cm caudal to the base of the scrotum to expose the penis, and the retractor penis muscle is retracted to expose the bulbospongiosus muscle, which covers the ventral aspect of the CSP. The right or left edge of the bulbospongiosus muscle is elevated from the edge of the urethral groove to expose 4 to 5 cm of the underlying tunica albuginea of the CSP. A 3-cm longitudinal incision is made through the tunica albuginea of the CCP adjacent to the CSP to expose the sinusoidal spaces of the CCP, and stagnant blood is evacuated from the cavernous spaces of the CCP through this incision using irrigation as described earlier (Fig. 66-11).

A matching 3-cm longitudinal incision through the tunica albuginea of the CSP is created adjacent to the 3-cm incision into the CCP. The urethral catheter compresses the sinusoidal spaces of the encircling CSP, so the CSP must be incised carefully to avoid extending this incision into the lumen of the urethra. Bright red blood hemorrhages from the incised CSP, and at this point in the procedure, suction is usually required to maintain visibility. The medial edge of the incision in the tunica albuginea of the CCP is sutured to the lateral edge of the incision in the tunica albuginea of the CSP with 3-0 or 2-0 absorbable suture using a simple-continuous suture pattern. To complete the shunt, the lateral edge of the incision into the CCP is sutured to the medial edge of the incision into the CSP using a simple-continuous suture pattern. The bulbospongiousus muscle is sutured to its origin on the tunica albuginea of the CCP at the edge of the urethral groove, and the subcutaneous tissue and skin are apposed. Horses appear to suffer no discomfort after the surgery, and swelling is minimal. The stallion should receive no sexual stimulation for at least a month after surgery.

Complications of the cavernosal shunt in men include urethrocavernous or urethrocutaneous fistula, penile gangrene, infection, and a painful CSP during erection. Men receiving a shunt for treatment for priapism may become impotent from failure to achieve or maintain pressure in the CCP required for intromission, and this failure can be the result of damaged cavernous tissue or from the shunt itself. The shunt may close as normal blood outflow in the CCP resumes, but whether closure is essential for return of potency is not known. Bulls may become impotent after developing a trauma-induced shunt between the CCP and CSP, but a shunt created surgically between the CCP and CSP...
the CSP of normal stallions does not seem to interfere with subsequent erection and ejaculation, even if the shunt does not close. In one report, a stallion that developed penile paralysis after suffering from priapism for several days regained normal erectile and ejaculatory function within 1 year after resolution of priapism, even though the horse had received two shunts between the CCP and the CSP. Failure of a stallion affected by priapism to develop a normal erection after creation of a shunt between the CCP and the CSP is most likely the result of damage to erectile tissue caused by protracted priapism, rather than by the shunt. Erectile function in men with cavernosal tissue damaged by protracted priapism has been enhanced by injecting a vasoactive drug, such as papaverine, phenoxybenzamine, or phentolamine, into the cavernosal tissue. Administering a vasoactive drug into the cavernous tissue may likewise be useful for enhancing erectile function of horses with damaged erectile tissue. Some stallions with damaged erectile tissue may regain the ability to achieve intromission if they are assisted in placing their penis into the vagina of the mare, and some may be trained to ejaculate into an artificial vagina. If a stallion has decreased penile sensitivity resulting from damage to the pudendal nerves caused by priapism, an antidepressive drug, imipramine, can be administered before breeding to lower the stallion’s ejaculatory threshold.

PHALLECTOMY
Phallectomy may be necessary if all other treatments to relieve priapism fail (see “General Surgical Procedures,” p. 829). Hemorrhage during or after phallectomy may be no worse than that expected during and after amputation of the penis of a horse not affected by priapism.

Intersex
Clinical Features
Anomalous development of the external genitalia of intersexes confuses their sexual identification. The most common intersex, the male pseudohermaphrodite, usually has a rudimentary penis, which resembles an enlarged clitoris, and prepuce, which resembles a vulva, situated on the midline somewhere between the ischial arch and the normal, ventral abdominal location of the preputial orifice (see Fig. 65-10). Its testes are usually located within the abdomen or inguinal canals or hidden subcutaneously beneath a moderately developed udder (see Chapter 65). Despite its deceptive feminine appearance, the intact male pseudohermaphrodite displays masculine behavior and is even capable of achieving an erection of the rudimentary penis.

Treatment
If the genitalia are located close to the ischium, the pseudohermaphrodite’s appearance can be altered to more closely resemble that of a female by amputating the rudimentary penis and constructing a vulva using the prepuce. Alternatively, if the genitalia are less than 15 cm caudal to the inguinal area, the male pseudohermaphrodite’s appearance can be altered to more closely resemble that of a male by cranially rotating the genitalia to a more normal position.

NEOPLASIA
Incidence and Etiology
The incidence of neoplasia of the external genitalia is second only to that of the skin. Neoplasms of the penis and prepuce include squamous papillomas, squamous cell carcinomas, sarcomas, melanomas, mastocytomas, and hemangiomas. Melanomas are occasionally found on the prepuce of old gray horses, and squamous papillomas, the benign counterparts of squamous cell carcinoma, are often found on the external genitalia of young horses or adjacent to penile or preputial carcinomas of old horses. Squamous cell carcinoma is by far the most common penile and preputial neoplasm.

Genital squamous cell carcinoma may arise de novo or from malignant transformation of a squamous papilloma. Any papillomatous lesion present on the penis or prepuce of a horse should be considered to be premalignant.

Squamous cell carcinoma is usually found on old horses, especially those of breeds with nonpigmented genitalia, such as Appaloosas and American Paint horses. Lack of preputial or penile pigmentation seems to predispose to carcinoma, even though the external genitalia are not exposed to direct sunlight. One study performed on mice showed that squamous cell carcinoma may be caused by unidentified carcinogenic agents in smegma, but another study, also performed on mice, which used human smegma, was not able to substantiate this finding. Regardless of whether smegma contains a carcinogenic agent, it may stimulate neoplastic changes in penile and preputial integument by causing chronic irritation. Geldings and old horses, therefore, may be predisposed to development of genital squamous cell carcinoma, because they produce a greater amount of smegma than do young horses and stallions.

Squamous cell carcinoma occurs most commonly on the glans and internal lamina of the prepuce. Penile and preputial squamous cell carcinomas are locally invasive but have a low grade of malignancy and grow surprisingly slowly for carcinomas. Metastasis to the superficial and deep inguinal lymph nodes occurs late in the disease. In one study, 12% of 48 horses affected with penile or preputial squamous cell carcinoma had metastatic involvement of the inguinal lymph nodes.

Diagnosis
Most affected horses are presented for examination when the owner observes the lesion, but some may be presented because of a malodorous, purulent, blood-stained, preputial discharge. The duration of disease is usually unknown but lengthy, because most owners inspect their horse’s penis infrequently. Precancerous lesions may appear as a small, heavily keratinized plaque, and cancerous lesions may first appear as a shallow, flat ulceration with an indurated base. Longstanding carcinomas may attain a cauliflower-like excrescence, containing areas of necrosis, ulceration, and hemorrhage, that can interfere with coitus or normal protrusion and retraction of the penis (Fig. 66-12).
tumor can cause dysuria by impinging on the urethra. Most affected horses are also affected by balanoposthitis.71, 74 Metastatic spread of penile and preputial squamous cell carcinoma can sometimes be palpated as an enlargement of the inguinal lymph nodes, but mild, metastatic enlargement of the inguinal lymph nodes may be difficult to differentiate from lymphadenopathy secondary to balanoposthitis.73 Penile or preputial squamous cell carcinoma can metastasize to internal organs without causing gross enlargement of the inguinal lymph nodes.80

Treatment

A variety of treatments for horses affected with squamous cell carcinoma of the penis or prepuce have been described, including surgical excision, cryosurgery, chemotherapy, and hypothermia.

SURGICAL EXCISION

A small lesion on the prepuce can be excised and the wound sutured. Using a carbon dioxide laser to locally excise squamous cell carcinoma from the external genitalia may decrease the incidence of recurrence of the neoplasm.81 Using a laser to excise a neoplasm not only decreases postoperative swelling by sealing lymphatic vessels but also has a thermal, killing effect on marginal tumor cells.82 Horses with extensive neoplastic lesions of the external genitalia require preputial reefing or phallectomy (see “General Surgical Procedures,” p. 827). Occasionally, neoplasms become so extensive that prescrotal urethrostomy combined with en bloc resection of the penis, prepuce, and inguinal lymph nodes becomes necessary.83

CRYOTHERAPY

Cryotherapy is a useful treatment of horses with early lesions of squamous cell carcinoma. Cryotherapy can be performed using liquid nitrogen administered as a spray or through a cryoprobe, or using CO2 administered through a cryoprobe. Thermocouple needles and a pyrometer (i.e., tissue temperature indicator) are used to monitor the depth and degree of freezing. A double, fast-freeze-slow-thaw cycle gives the best results.84 More information on cryosurgery is found in Chapter 15.

CHEMOTHERAPY

Horses with small genital lesions of squamous cell carcinoma have been treated successfully by applying 5% 5-fluorouracil to the lesions at 14-day intervals.85 Lesions need not be debulked, provided that the lesion is raised no more than to 2 to 3 mm above the surrounding integument. Up to seven treatments may be required to effect resolution of lesions. The drug is also effective in causing regression of preneoplastic lesions to which it is applied.

Horses with squamous carcinoma of the external genitalia have been treated by intratumoral injection of cisplatin in sesame oil.86, 87 The drug is administered at a dosage of 1 mg/cm³ tissue every 2 weeks, usually until the tumor has been injected four times. Intratumoral chemotherapy with cisplatin can be used alone for treatment of horses with small tumors or in combination with surgery for treatment of horses with large tumors. Tumor cells still present after the tumor has been excised or debulked are stimulated into active proliferation and hence are more susceptible to cisplatin. Administration of cisplatin treatments intra-operatively and at 2-week intervals appears to result in a better outcome, at least for horses with tumors that have a high proliferation index, than does delaying chemotherapy until the wound has healed.87 Injecting the tumor bed and a margin of normal tissue with cisplatin at the time of surgery and during all phases of wound healing does not have clinically apparent detrimental effects on healing of wounds closed primarily or wounds left open to heal by secondary intention.86, 87 (For more information on skin tumor treatments, and chemotherapy in general, see Chapter 29.)

HYPOTHERMIA

Radiofrequency-induced hyperthermia has been used to treat horses with sarcoids and cattle and horses suffering from ocular neoplasia.89, 90 Although its use to treat horses with genital neoplasia has not been reported, radiofrequency-induced hyperthermia could be useful for treatment of horses with genital neoplasia. Intratumoral hyperthermia is induced by a radiofrequency current of 2 MHz. Using this treatment, the tumor is heated to approximately 50°C for 30 seconds. Large tumors are heated in sections. Multiple
treatments are required, but the length of the interval between treatments is determined subjectively.

Prognosis
In one study of 48 male horses with genital carcinoma, 64.5% of horses were alive 18 months after surgical therapy. In another study, about 81% of 45 affected horses survived at least 1 year after surgical therapy with no evidence of recurrence of the disease. Both studies found that prognosis for survival was poor if squamous cell carcinoma had metastasized to the inguinal lymph nodes.

Invasion of the cavernous tissue by squamous cell carcinoma is a pejorative prognostic factor for survival in men and is likely to be so in horses as well, because neoplastic invasion into a corporeal body may be more likely to result in hematogenous spread of the neoplasm. In one study, three of four horses that had metastases of penile carcinoma to the abdomen had gross or histologic evidence that the neoplasm had invaded the cavernous tissue.

Horses that have corporeal invasion by a carcinoma seem to have a high likelihood of abdominal metastases, and therefore, laparoscopic examination of the abdomen of a horse that has neoplastic invasion of a corporeal body may be prudent. Because lesions of squamous cell carcinoma sometimes recur, horses should be monitored periodically for recurrence of disease after apparently successful treatment.

Habronemiasis
Etiology
Cutaneous habronemiasis, also known as "summer sore" or granular dermatitis, is a granulomatous, mildly pruritic disease caused by cutaneous migration and encystment of the larvae of the equine stomach worm *Habronema*. Larvae passed in the feces are ingested by fly maggots, and after the maggot pupates, the larvae are deposited on wounds from the feeding fly. The disease appears in spring and summer, when flies are prevalent, and usually disappears with onset of cold weather. The penis and prepuce are common sites of infestation by these larvae because moisture on these structures attracts flies. Horses that tend to extend their penis while resting and horses that receive anthelmintic drugs infrequently may be more prone to developing genital habronemiasis.

Pathophysiology
Infestation stimulates an acute granulomatous reaction characterized by exuberant granulation tissue that contains numerous small, yellow, hard, caseous granules composed of eosinophils, nuclear remnants, and larvae. The larvae may excrete a substance lytic to the host's tissue, but a local hypersensitivity reaction to the larvae resulting from repeated reinfection is probably responsible for the extreme granulomatous response. The presence of mature *Habronema* in the stomach may induce a state of general hypersensitivity, because horses affected by cutaneous habronemiasis are almost always heavily parasitized by adult worms. Some horses appear to be more susceptible and are plagued by yearly recurrence of lesions.

Clinical Signs
The preputial ring and urethral process are the genital sites of predilection. Preputial lesions may appear as ulcerated, red areas demarcated by edges of depigmentation. Lesions may be granulomatous and extensive (Fig. 66-13). The infested urethral process may be enlarged from periurethral fibrosis, and hyperemic prolapsed mucous membrane may protrude from the urethral orifice. Preputial lesions may mechanically impede the telescoping action of the preputial laminae, and lesions of the urethral process may cause partial obstruction to the flow of urine. A horse with a distorted urethral process may spray itself or show signs of discomfort during urination. Erosions into the CSP may result in hemorrhage at the end of urination or ejaculation. Horses with a genital lesion of cutaneous habronemiasis may have lesions of cutaneous habronemiasis elsewhere on the body.

Diagnosis
Cutaneous habronemiasis of the external genitalia is usually diagnosed by its typical appearance, but lesions can be confused with squamous cell carcinoma, exuberant granulation tissue, or phycomycosis. A nonhealing, granulating wound accompanied by marked circulating eosinophilia is suggestive of the disease. Squeezing the lesion may cause granules to extrude, and occasionally a larva may be found if exudate is squeezed onto a slide and examined microscopically. Eosinophils, multinucleated giant cells, granules, and, sometimes, cross-sections of larvae can be seen by examining affected tissue histologically.

Treatment
NONSURGICAL TREATMENT
Lesions are resolved by eliminating the larvae or by reducing the horse's hypersensitivity to them. Ivermectin, administered orally at 200 µg/kg, or organophosphates administered topically, orally, or intravenously have been effective in destroying the larvae. Prednisolone, administered orally at 1.5 mg/kg once a day for 10 to 14 days, or diethylcarbamazine, administered orally at 1.5 mg/kg twice a day for segmental posthetomy.

![Image](image_url)
7 to 14 days, has brought about resolution of lesions by diminishing the body's response to the larva. Daily topical application of a cream containing an organophosphate, such as trichlorfon, and a corticosteroid, such as dexamethasone, may bring about resolution of small granulomatous lesions caused by cutaneous habronemiasis.

SURGICAL TREATMENT
Elliptical or circumferential resection of fibrotic areas of the internal lamina of the prepuce caused by chronic infestation may be required to restore normal preputial function, and amputation of an affected urethral process may be required to restore normal urination or to prevent hemospermia.

Hemospermia
Etiology
Hemospermia, or blood in the ejaculate, is an important cause of infertility of stallions and has been attributed to bacterial urethritis occurring usually at the area of the ejaculatory ducts; habronemiasis or neoplasia of the urethral process; improperly fitted stallion rings; seminal vesiculitis; and trauma to the urethral process or glans penis. Viral urethritis has been suspected, but not proven, to cause hemospermia. Hemospermia has been reported to occur from urethral rents, the etiology of which is unknown. The source of voluminous hemorrhage in the ejaculate is usually the CSP. Hemorrhage from the CSP typically occurs at the end of ejaculation when contraction of the bulbospongious muscle causes pressure within the CSP to increase from 17 to nearly 1000 mm Hg.

Red blood cells in the ejaculate are associated with reduced fertility, even though seminal quality appears otherwise unaffected, because red blood cells are spermicidal. The condition may be more common in Quarter Horses and frequently bred stallions are more often affected.

Diagnosis
Stallions affected by hemospermia may require several mounts to ejaculate and sometimes exhibit pain during erection or ejaculation. Blood in the semen is most easily identified by collecting the stallion’s ejaculate with an artificial vagina. Semen of affected horses is usually pink to red, but because blood in amounts too minute to be detected grossly can cause infertility, microscopic examination of the semen may be necessary to detect the condition. Microscopic examination of semen may also reveal a large number of white blood cells if septic seminal vesiculitis is the cause of hemospermia.

Septic seminal vesiculitis, an occasional cause of hemospermia, may be detected by identifying numerous clumps of purulent material in the semen and by finding blood in the gel fraction of the ejaculate. A thickened vesicle filled with echogenic fluid may be seen during transrectal ultrasonographic examination of a septic seminal vesicle. The causative organism of septic, seminal vesiculitis can be cultured from fluid obtained directly from the infected seminal vesicle.

Rents in the urethra, a common cause of hemospermia, can be detected by examining the urethra with a sterilized, flexible endoscope that is at least 100 cm long. A urethral tear into the CSP appears endoscopically as a 5- to 10-mm-long, linear defect on the convex surface of the urethra, distal to the openings of the bulbourethral glands, near the level of the ischial arch. The shaft of a hypodermic needle can be introduced percutaneously into the lumen of the urethra at the level of the ischial arch during endoscopic examination to confirm the location of the defect (Fig. 66-14). By endoscopically examining the urethra of a horse affected with hemospermia immediately after ejaculation, the examiner may be able to observe blood emanating from an otherwise undetectable rent.

Urethrography to diagnose urethral lesions has been described. The penis is radiographed after injecting 180 mL of barium suspension into the urethra. The barium is allowed to drain, 180 mL of air is injected to provide double contrast, and the penis is again radiographed. Bacterial and viral cultures and biopsy and histologic examination of urethral lesions may establish the cause of urethritis.

Treatment
NONSURGICAL TREATMENT
Sexual abstinence seems to be important in the treatment of stallions affected with hemospermia, regardless of the origin, because erection and contractions of the bulbospongious muscle during ejaculation dilate and further traumatize the urethra. Medical treatment of affected horses has included intravenous administration of formaldehyde solution, oral administration of methenamine, and systemic administration of antimicrobial drugs.

Horses affected with hemospermia caused by septic seminal vesiculitis should receive antimicrobial therapy that is effective against the causative organism. Systemic

Figure 66-14. Endoscopic view of a urethral rent. The shaft of a hypodermic needle has been inserted percutaneously into the lumen of the urethra at the level of the ischium to pinpoint the location of the defect.
administration of antimicrobial drugs to stallions affected with septic seminal vesiculitis is often ineffective because antimicrobial drugs diffuse poorly into the gland. Infusing the appropriate antimicrobial drug directly into the seminal vesicles after the vesicles have been lavaged may be a more effective treatment. Horses with low-grade hemospermia can sometimes be managed by adding an extender to the semen to dilute the effect of the red blood cells on the spermatozoa.

**SURGICAL TREATMENT**

Temporary perineal urethrostomy combined with sexual rest has been effective in eliminating hemospermia caused by a urethral lesion. Eleven of 15 affected horses were successfully treated by temporary subischial urethrostomy and daily installation of suppositories of nitrofurazone and hydrocortisone into the urethra, although two stallions developed a urethral fistula. These investigators offered no sound rationale for the relatively high incidence of success of temporary urethrostomy, but other investigators implied that topical application of antimicrobial drugs to lesions of bacterial urethritis is responsible for resolution of hemospermia. More likely, success of temporary subischial urethrostomy in eliminating hemospermia should be attributed to decreased pressure in the CSP and diversion of blood flow from the urethral lesion. When the bladder has been emptied, the bulbospongious muscle contracts to expel urine that remains in the urethra. Incising the CSP at the ischium decreases cavernosal pressure at the end of urination and diverts blood flow from the urethral lesion to the temporary urethrostomy, thus permitting healing of the urethral mucosa and underlying tunica albuginea of the CSP. Simply incising the convex surface of the tunica albuginea of the CSP at the ischium, without exposing the lumen of the urethra, may be as effective as temporary urethrostomy for eliminating hemospermia, and the risk of the stallion’s developing a urethral fistula is eliminated. This theory, however, has not been clinically evaluated.

**Hematuria**

**Etiology**

Hematuria can originate from the kidney, ureter, bladder, urethra, or reproductive organs. Causes of hematuria include renal, ureteral, vesicular, or urethral calculi; renal, and vesicular neoplasia; and pyelonephritis. Terminal hematuria (i.e., hematuria that occurs at the end of urination) is associated with a lesion located at the proximal portion of the urethra and the trigone of the bladder. Hematuria associated with a rent of unknown cause at the proximal portion of the urethra has been observed in geldings. The urethral rent appears to be identical to that often seen in stallions with hemospermia (see "Hemospermia," earlier).

The cause of urethral rents is idiopathic, but the reason why the rent occurs invariably at the level of the ischial arch may be explained by the anatomy of the urethra. The diameter of the urethral lumen is approximately 1 to 1.5 cm at the origin of the urethra. The lumen dilates to 3.5 to 5 cm in the pelvic portion of the urethra (i.e., at the pars pelvina) and decreases dramatically in diameter to 1 to 1.5 cm where the urethra bends sharply as it crosses the ischial arch. The sharp turn and the narrowing of the urethral lumen in the area of the ischial arch may expose the convex surface of the urethra at the level of the ischial arch to hydrodynamic forces not encountered by other portions of the urethra.

**Pathophysiology**

Because urethral rents communicate with the CSP, hemorrhage through the rent into the urethral lumen was thought to occur when pressure within this cavernosal space increases at the end of urination when the bulbospongious muscle contracts to expel the last vestige of urine. Recent research, however, showed that the rise in pressure within the CSP associated with contraction of the bulbospongious muscle is slight. Investigators theorized that the most likely explanation for hemorrhage at the end of micturition in horses with a urethral rent is that the intraluminal urethral pressure suddenly decreases at the end of urination while the pressure in the CSP remains high.

Even though the lesion in stallions is identical in appearance to that responsible for hematuria of geldings, the lesion in stallions rarely causes macroscopic hematuria. The reason for the difference in clinical signs between stallions and geldings is probably that during urination, pressure within the CSP of geldings is nearly double that of stallions. The CSP of geldings is not as well developed as that of stallions, and the difference in volume of the cavernosal space between geldings and stallions results in different pressures in the CSP at the end of urination.

**Diagnosis**

Blood in urine that results from a urethral rent is characteristically discharged at the end of urination (i.e., terminal hematuria). Occasionally, a horse with a urethral rent may show signs of dysuria, such as tenesmus at the end of urination. Endoscopic examination of the urethra reveals a 5- to 10-mm linear urethral defect on the convex surface of the urethra, distal to the openings of the bulbourethral glands, near the level of the ischial arch. Gross evidence of inflammation around the defect is not observed.

**Treatment**

Some urethral rents heal spontaneously, but horses with hematuria caused by a urethral rent can be treated successfully by temporary perineal urethrostomy (see “Temporary Perineal Urethrostomy,” p. 833, for a description of the surgical technique). Surgery eliminates hematuria, presumably by reducing vascular pressure in the CSP, which prevents escape of blood through a rent at the end of urination, thereby allowing the rent to heal. A perineal incision that extends into the CSP but does not penetrate the urethra seems to be as effective as temporary urethrostomy in eliminating hematuria and may reduce the risk of complications associated with temporary urethrostomy, such as development of a urethral fistula or stricture. Although horses may bleed substantially from the perineal wound, especially at the end of urination, macroscopic hemorrhage from the urethral orifice and evidence of pain during urination are not observed after surgery.
GENERAL SURGICAL PROCEDURES

Segmental Postthetomy

**Indications**

Segmental postthetomy, or resection of a circumferential segment of the internal preputial lamina, is indicated for removal of preputial neoplasms, granulomas, or scars so extensive that simple excision of the lesion is impossible. Other terms for the procedure include posthioplasty, circumcision, and reefing. Provided that the preputial lesions do not involve the underlying tunica albuginea, penile amputation can be avoided by segmental postthetomy. With removal of most of the internal lamina of the prepuce, a paralyzed penis can be maintained permanently within the preputial cavity.

**Surgical Technique**

Segmental postthetomy can be performed with the horse standing after anesthetizing the pudendal nerves (see "Diagnostic Procedures," earlier), but the procedure is most easily and safely accomplished with the horse anesthetized and positioned in dorsal or lateral recumbency. The urethra is catheterized, and the penis is extended by traction on gauze looped around the collum glandis. A tourniquet placed proximal to the surgical site may facilitate surgery. Parallel circumferential incisions through the preputial epithelium are created distal and proximal to the lesion, and these incisions are connected by a longitudinal incision (Fig. 66-15). Care must be taken to avoid severing the large, longitudinal, subcutaneous branches of the external pudendal arteries and veins that lie superficial to the tunica albuginea.

In cases where segmental postthetomy is performed to maintain a paralyzed penis within the external lamina of the prepuce, the distal circumferential incision should be made through the penile epithelium at the level where the internal preputial lamina inserts on the free body of the penis. The proximal circumferential incision should be made close to the preputial orifice.

**Figure 66-15.** Segmental postthetomy. A cuff of epithelium is removed from the shaft of the penis.

The cuff of integument between the incisions is dissected from the penis with scissors, taking care to avoid the large vessels. Normal alignment of tissue is maintained by placing four sutures at equidistant points around the circumference of the penis before the cuff of tissue is removed. The tourniquet is released, and all bleeding vessels are identified and ligated with absorbable sutures or cauterized. Loose adventitia is apposed with interrupted 2-0 absorbable sutures. The epithelium is apposed with interrupted no. 0 or 2-0 absorbable or nonabsorbable sutures.

**Aftercare**

Stallions should wear a stallion ring for at least 2 weeks and must be isolated from mares for 2 to 4 weeks. Regular exercise reduces postoperative edema. Nonabsorbable sutures should be removed 10 to 12 days postoperatively.

**Bolz Technique of Phallopecty**

**Indication**

The Bolz procedure is a technique used to permanently retract a paralyzed penis into the preputial cavity and is performed to avoid phallectomy. This method of permanent retraction cannot be used if the penis or internal lamina of the prepuce is badly damaged or if the horse is still capable of attaining an erection. Damaged sections of prepuce, however, can be removed by segmental postthetomy during the same procedure.

**Surgical Technique**

The horse is anesthetized and positioned in dorsal recumbency. The urethra should be catheterized for easy identification. A 10-cm longitudinal incision is made on the perineal raphe just caudal to the scrotum (Fig. 66-16, A), and the penis is bluntly separated from surrounding fascia, taking care to avoid damaging the surrounding large pudendal vessels (see Fig. 66-16, B). The penis is retracted until the annular ring of the reflection of the internal preputial lamina onto the free body of the penis is visible at the cranial extent of the incision (see Fig. 64-16, C). The penis is anchored in this position with two heavy, nonabsorbable percutaneous sutures through the annular ring on each side of the penis.

The anchoring sutures should penetrate the skin 2 to 4 cm from the incision at about the level of the middle of the incision. The sutures are inserted through the annular ring on the lateral surface of the penis, taking care to avoid entering the preputial cavity, the urethra, or cavernous tissue. An assistant should palpate the fornix of the preputial cavity during placement of the sutures through the annular ring to ensure that the sutures do not penetrate the preputial epithelium. The sutures exit the skin 2 to 3 cm from their entry points. They are tightened until the glans penis is flush with the preputial orifice and tied over rolls of gauze or large buttons to prevent the suture from cutting through the skin (see Fig. 66-16, D). The subcutaneous tissue and skin are each closed separately.

The percutaneous anchoring sutures are removed after 10 to 12 days; at this time, adhesions of sufficient strength to maintain the penis in its retracted position have formed.
Necrosis of skin beneath the rolls of gauze is inevitable, but the technique allows adjustment of tension on the percutaneous sutures and repositioning of the penis. Precise positioning of the penis in the prepuce is important because, if the penis is inadequately retracted, the glans penis may protrude excessively through the preputial orifice, or if the penis is excessively retracted, the horse may develop urine scald from urinating in the preputial cavity. Two heavy absorbable sutures, substituted for the nonabsorbable percutaneous sutures, can be used to anchor the annular ring to the subcutaneous fascia. Necrosis of skin is avoided, but the sutures cannot be adjusted after surgery.

Aftercare
The horse should be walked daily to minimize swelling, and heavy exercise can be resumed 2 to 3 weeks after skin sutures have been removed. Retraction distorts the penis into a sigmoid curvature with acute bends, but penile blood supply and urination remain unaffected. The horse can be castrated during the same procedure, using either an inguinal or a scrotal approach. The incision should be sutured because an open inguinal or scrotal wound may interfere with healing around the anchoring sutures. If the horse is castrated before the procedure and the scrotal wound is left unsutured to heal by secondary intention, the surgeon is confronted with the tedious task of caring for the protruded penis for several weeks while the scrotal incision heals.

Amputation of the Urethral Process
Indications
The urethral process is most commonly excised to remove a granuloma caused by cutaneous habronemiasis, when the affected horse fails to respond to medical therapy. The urethral process is sometimes excised to remove a neoplastic lesion.

Patient Preparation
The urethral process can be amputated with the horse standing and sedated after infiltrating the base of the urethral process with a local anesthetic agent, but the procedure is most easily and safely accomplished with the horse anesthetized and in dorsal recumbency. The penis is prepared for aseptic surgery, and a urinary catheter is passed into the urethra. After placing traction on the urethral process with one or two Allis tissue forceps, two small-gauge needles (e.g., 23 or 25 gauge) are placed through the urethral process and the catheter at right angles to each other, proximal to the diseased portion of the urethral process (Fig. 66-17). These needles anchor the urethral process to...
the catheter, making the incised margin of the process more stable and accessible for suturing.

**Surgical Technique**

A circumferential incision extending through the skin, CSP, and urethral mucosa is made around the base of the urethral process proximal to the affected tissue and distal to the anchoring hypodermic needles. The urethral mucosa is apposed to the epithelium of the remaining stump of the urethral process, to anchor the urethral process to the catheter.

**Aftercare**

Stallions and recently castrated geldings should be isolated from mares for at least 3 weeks. Hemorrhage from the stump of the process, especially at the end of urination, should be expected for at least several days after amputation of the urethral process.

**Phallectomy**

**Indications**

Phallectomy is indicated when permanent penile paralysis is accompanied by irreparable penile damage, and more commonly, when neoplasia has invaded the tunica albuginea or is so extensive that more conservative treatment by cryosurgery, hyperthermia, local excision, or segmental postthetry is impossible. For geldings, phallectomy may be the most expedient means of treating urethral stenosis distal to the preputial orifice. Phallectomy of stallions is generally performed to salvage the horse for purposes other than breeding, but amputation of just the glans penis may not interfere with copulation.91

**Patient Preparation**

A stallion should be castrated 3 to 4 weeks prior to phallectomy, if possible, to avoid postoperative erection, which leads to hemorrhage and dehiscence. The procedure can sometimes be performed with the horse standing and sedated after anesthetizing the pudendal nerves (see "Diagnostic Procedures," earlier),28 but the procedure is most easily performed with the horse anesthetized and positioned in lateral or, preferably, dorsal recumbency. The urethra is catheterized with an equine male urinary catheter, and the penis is extended with gauze looped around the collum glandis. A tourniquet placed proximal to the proposed site of transection facilitates surgery.

**Surgical Techniques**

**VINSON'S TECHNIQUE OF PHALLECTOMY**

One of the simplest techniques of phallectomy is Vinsot’s procedure.43,112 A triangular section of tissue that includes epithelium, fascia, bulbospongious muscle, and CSP is removed from the ventrum of the penis proximal to the proposed site of transection, taking care not to enter the urethral lumen (Fig. 66-18). The triangle has a 2.5-cm base and 4-cm sides. Its apex points distally and is located about 4 or 5 cm proximal to the proposed site of transection. The exposed urethra is incised on its midline from the base to the apex of the triangle, and the incised edges of the urethra and the triangle’s epithelial border are apposed with simple-interrupted or simple-continuous absorbable sutures.97 The sutures should be closely spaced to compress the erectile tissue of the CSP. A simple-continuous suture pattern is probably more effective than a simple-interrupted suture pattern in compressing the erectile tissue of the CSP. The entire length of the process can be removed.

**Aftercare**

Stallions and recently castrated geldings should be isolated from mares for at least 3 weeks. Hemorrhage from the stump of the process, especially at the end of urination, should be expected for at least several days after amputation of the urethral process.
of the CSP. A simple-continuous suture pattern is probably more effective than a simple-interrupted suture pattern in compressing the erectile tissue of the CSP. The diseased portion of the penis is removed 4 to 5 cm distal to the urethrostomy using a wedge-shaped incision. Large vessels on the dorsal and lateral aspects of the tunica albuginea are ligated with absorbable suture, and the corporeal bodies are compressed with absorbable sutures placed through the tunica albuginea in an eveting or appositional pattern. The penile or preputial integument is sutured with absorbable or nonabsorbable sutures placed in an eveting or appositional pattern.

Instead of suturing the end of the stump, the surgeon can leave it unsutured to heal by secondary intention. To prevent hemorrhage from the corporeal bodies, a tightly fixed, non-absorbable ligature is placed around the penis 2 to 3 cm distal to the apex of the triangle, before the penis is transversely severed 1 to 2 cm distal to the ligature.

Rather than removing a triangle of tissue overlying the urethra, the technique can be simplified by making a 4- to 5-cm longitudinal incision into the urethral lumen. The incised edges of the urethra and the integument are apposed with simple-interrupted or simple-continuous absorbable sutures. These sutures incorporate and compress the cavernous tissue of the CSP. Vinsot’s technique, especially its modification, can often be performed with the horse standing. A primary disadvantage of the technique, or its modification, is the tendency of the urethra to stricture.

WILLIAMS’ TECHNIQUE OF PHALLECTOMY

The likelihood of urethral stricture is decreased when the Williams’ technique of phallectomy is employed. With this technique, a triangle of tissue with similar dimensions to those described in Vinsot’s technique is removed from the ventrum of the penis (Fig. 66-19, A). The triangle’s apex is directed proximally, rather than distally, and the base of the triangle is the site of penile transection. The urethra is split on its midline from the base to the apex of the triangle, and the incised edge of the urethra and the triangle’s epithelial edge are apposed with simple-interrupted or simple-continuous absorbable sutures. These sutures incorporate and compress the cavernous tissue of the CSP. A simple-continuous suture pattern is probably more effective than a simple-interrupted suture pattern in providing compression.

Figure 66-19. A, Williams technique of phallectomy. A triangle is removed from the ventrum of the penis. The triangle’s apex is directed proximally. The urethra is split on its midline from the base to the apex of the triangle, and the edges of the urethra and the triangle’s epithelial edges are apposed with simple-interrupted absorbable sutures. B, The base of the triangle is left unsutured. The urethral catheter is removed, and the penis is obliquely transected at the base of the triangular urethrostomy in a craniodorsal direction. C, The stump is closed with interrupted sutures that pass through the urethra, the tunica albuginea of the urethral groove, and the tunica albuginea of the dorsum of the corpus cavernosum penis (CCP) and the penile or preputial epithelium. The sutures should be pre-placed at equidistant intervals for an even closure. D, The sutures are tightened and tied, compressing the cavernous spaces, and the epithelium is apposed to the urethral mucosa.
The base of the triangle is left unsutured. The urethral catheter is removed, and the penis is obliquely transected at the base of the triangular urethrostomy in a craniodorsal direction, so that the dorsum of the penile stump is longer than the ventrum (see Fig. 66-19, B). Large branches of the external pudendal vessels that reside in loose fascia on the dorsal and lateral aspects of the tunica albuginea are ligated with absorbable suture.

The stump is closed with interrupted absorbable or nonabsorbable sutures that pass through the urethra, the tunica albuginea of the urethral groove, and the tunica albuginea of the dorsum of the CCP and the penile or preputial epithelium (see Fig. 66-19, C). The sutures should be pre-placed at equidistant intervals for an even closure. When these sutures are tightened and tied, the erectile bodies are compressed, and the epithelium is apposed to the urethral mucosa (see Fig. 66-19, D). Alternatively, the stump can be closed in two layers by first suturing the tunica albuginea of the dorsum of the CCP to the tunica albuginea of the urethral groove with interrupted absorbable sutures placed at bisecting intervals and by suturing the penile or preputial integument to the urethral mucosa with interrupted absorbable or nonabsorbable sutures.

SCOTT’S TECHNIQUE OF PHALLECTOMY
With this technique, a circumferential transverse incision through the epithelium of the body of the penis or prepuce is made at the intended site of transection, and branches of the external pudendal vessels are ligated. Dissection is continued through the CCP to the urethral groove. The CSP is circumferentially incised to the urethra, which is easily identified by the urinary catheter in its lumen, and a 4- to 5-cm segment of urethra is dissected free from the amputated section of penis (Fig. 66-20, A).

Figure 66-20. Scott’s technique of phallectomy. A, A circumferential transverse incision through the epithelium of the body of the penis or prepuce is made at the intended site of transection. Dissection is continued through the corpus cavernosum penis (CCP) to the urethral groove. The corpus spongiosum penis (CSP) is circumferentially incised to the urethra, and a 4- to 5-cm segment of urethra is dissected free from the amputated section of penis. B, The stump of the CCP is closed by apposing the outer perimeter of its tunica albuginea to the tunica albuginea of the urethral groove with interrupted absorbable sutures pre-placed at equidistant intervals. C, The sinusoidal spaces of the CSP are closed by suturing the tunica albuginea surrounding the CSP to the submucosa of the urethra with interrupted absorbable sutures. D, The urethral stump is stretched and folded back over the end of the penis, where it is sutured to the penile or preputial epithelium and underlying tunica albuginea.
PHALLECTOMY BY EN BLOC RESECTION WITH PENILE RETROVERSION

Removal of the free portion of the penis, the internal lamina and external lamina of the prepuce, and regional lymph nodes may be indicated when these structures are extensively affected with neoplasia. With this technique of phallectomy, a fusiform incision is created around the preputial orifice. The incision begins 6 cm cranial to the orifice and ends 10 cm caudal to it. The incision is carried to the deep fascia of the abdominal tunic, and if neoplasia has metastasized to the superficial lymph nodes, dissection is extended through this plane to both superficial inguinal rings, and the superficial inguinal lymph nodes are removed. The penis is amputated approximately 6 to 8 cm caudal to the fornix of the prepuce, and the amputated portion of the penis and the prepuce are removed en bloc. The technique can be modified by amputating the penis using Williams' or Vinsot's technique of phallectomy.

By bluntly separating penile fascia, the stump of the penis is retroverted through a 6-cm subischial incision created approximately 20 cm ventral to the anus, so that its distal end points caudally and extends just beyond the subischial incision (see Fig. 66-21, B). The tunica albuginea of the CCP and the fascia of the penis are sutured to the subcutaneous tissue of the subischial incision. The ventral aspect of the urethra is incised longitudinally over its 4-cm length, and the edges of the urethra are sutured to the surrounding edges of the incised subischial skin. Penrose drains are placed deeply at the cranial incision, and the subcutaneous tissue and skin are each closed separately.

PHALLECTOMY BY EN BLOC RESECTION WITHOUT PENILE RETROVERSION

This technique of phallectomy is similar in many respects to phallectomy by en bloc resection with penile retroversion, but with this technique, the stump of the penis is not retroverted but is maintained in its normal ventral position. With this technique, a fusiform incision is created on the midline to a point 10 cm caudal to the preputial orifice. The caudal portion of the incision is extended and deepened to expose and remove the inguinal lymph nodes, if neoplasia has metastasized to these structures.

Blunt dissection is continued into the loose areolar tissue of the prepuce, ligating large vessels as they are encountered. After the shaft of the penis is exposed, dissection is redirected along the shaft of the penis in a plane superficial to the subcutaneous tissue overlying the vasculature of the penis. At least 10 cm of the shaft should be exposed. A tourniquet is applied around the shaft of the penis proximal to the site of amputation. The dorsal arteries and veins of the penis are ligated and transfixed to the tunica albuginea. The penis is transected caudal to the fornix of the prepuce, using the method described by Williams. After the tourniquet is removed, the stump is fixed to the body wall on the midline with heavy absorbable interrupted sutures. The subcutaneous tissue cranial to the penile stump surrounding the exposed penile shaft is apposed. Skin is sutured to the tunica albuginea and the urethral mucosa of the new urethral orifice. The skin cranial and caudal to the urethral orifice is sutured.
This technique of en bloc resection requires a smaller incision and results in less alteration to the appearance of the horse than does the retroversion technique, while still allowing the surgeon to remove extensive portions of the penis and extirpate the regional lymph nodes.115

Aftercare
Because the procedure is generally performed to salvage the horse for purposes other than breeding, stallions should be castrated several weeks in advance of phallectomy. Stallions and recently castrated geldings should be isolated from mares for 2 to 3 weeks and should wear a stallion ring on the penile stump during this time.

Complications
Hemorrhage from the penile stump, especially at the end of urination, should be expected for at least several days after phallectomy. Hemorrhage usually emanates from the CSP. Phallectomy of geldings is attended by less hemorrhage than phallectomy of stallions. Excessive hemorrhage may be accompanied by minor dehiscence, which is usually of no consequence. Dehiscence of sutured erectile tissue may lead to the formation of a large hematoma. Other complications of phallectomy in the immediate postoperative period include pain, infection of the surgical wound, edema of the prepuc, and acute urinary obstruction caused by edema of the urethra.73,74,83,115 Long-term complications include cystitis, urine scalding, dysuria caused by urethral stricture, recurrence of neoplasia at the site of amputation, and neoplastic metastases to inguinal lymph nodes and internal organs.

Temporary Perineal Urethrostomy
Indications
Temporary urethrostomy at the ischial arch is performed to provide access to small cystic calculi, for treatment of horses affected with hemospermia or hematuria, and to divert the flow of urine from the penile urethra for such conditions as urethral laceration or urethral urolithiasis.

Surgical Technique
Temporary perineal urethrostomy is best performed with the horse standing and sedated after administering epidural anesthesia or infiltrating the tissue at the proposed site of incision with a local anesthetic agent. A 6- to 8-cm vertical incision is created on the perineal raphe about 2 to 3 cm below the anus. The incision is extended through the skin, the retractor penis and bulbospongious muscles, the CSP, and the urethral mucosa (see Fig. 66-2).

Preoperative insertion of a large-bore urethral catheter facilitates identification of the urethra. The perineal incision should “funnel” to a short urethral incision as it deepens to avoid postoperative pocketing of urine in the tissues. If the incision strays from the midline, profuse hemorrhage can result from laceration of branches of the external pudendal artery.36 The urethrostomy is generally allowed to heal by secondary intention; development of clinically apparent urethral stenosis after this procedure is rare. The urethrostomy normally heals within 2 weeks.804

CHAPTER 67

Vulva, Vestibule, Vagina, and Cervix
Brett Woodie

The caudal aspect of the reproductive tract is composed of the vulva, vestibule, vagina, and cervix. These structures are susceptible to a variety of injuries during breeding and foaling. Conformational abnormalities of the caudal reproductive tract may predispose the mare to pneumovagina, urovagina, and other problems. Ultimately, problems associated with the caudal reproductive tract can lead to infertility.

VULVA, VESTIBULE, VAGINA, AND CERVIX

The external genitalia of the mare are composed of the perineum and the vulva. The perineum is the region bound dorsally by the base of the tail, laterally by the semimembranosus muscles and sacrosciatic ligaments, and ventrally by the ventral commissure of the vulva (Fig. 67-1). The fibromuscular perineal body lies between the anus and the vulva. Fibers of the external anal sphincter and the constrictor vulvae muscles form the perineal body (Fig. 67-2).

The vulva includes the two labia and the clitoris. The external orifice of the vulva is typically 12 to 15 cm long. When the architecture of the external genitalia of the mare is normal, the labia of the vulva are vertical and meet dorsally to form the dorsal commissure, which is located just ventral to the anus. The labia meet ventrally to form the ventral commissure, which is located just ventral to the ischial arch. Approximately two thirds of the vulvar cleft is ventral to the ischial arch. Normally, the labia of the vulva are muscular and resist manual separation, as a result of the paired constrictor vulvae muscles, which lie deep to the skin of the labia. The internal pudendal vessels provide...
The clitoris in the mare is the homolog of the penis in the male. It is located laterally and ventrally. The body of the clitoris is approximately 5 cm in length and is attached to the ischial arch by two crura.

The vestibule is the terminal part of the internal genital tract. It is a tubular structure approximately 12 to 15 cm long that connects the vulva to the vagina. The normal configuration of the vestibule is a ventrodorsal slope in the rostral direction. The cranial extent of the vestibule ends at the level of the transverse fold, which is located dorsal to the external urethral orifice. The lateral and ventral surface of the vestibule is covered by the constrictor vestibuli muscles, which dorsally are incomplete. The paired constrictor vestibuli muscles blend caudally with the constrictor vulvae muscles. The constrictor vestibuli muscles, the pillars of the hymen, and the floor of the pelvis meet to form the vestibular sphincter.

The vagina is a tubular structure extending cranially from the transverse fold of the external urethral orifice to the vaginal fornix around the cervix. The vagina is related to the rectum dorsally, to the bladder and urethra ventrally, and laterally to the pelvic wall. The majority of the vagina is located retroperitoneally, but a small cranial portion of the ventral aspect and larger portions of the dorsal aspect are always covered with peritoneum. The extent to which the cranial part of the vagina is covered with peritoneum is related inversely to the fullness of the rectum and bladder. The vascular supply of the vagina is derived from the internal pudendal vessels. Since there is no skeletal muscle present in the vagina, there is no motor innervation. Multiple sympathetic ganglia are present in the vaginal wall.

The cervix is an extension of the uterine body, with the caudal portion positioned in the cranial aspect (fornix) of the vagina. The caudal portion of the cervix is referred to as the external cervical os, and it is covered by vaginal mucosa. The cervix is a tubular muscular structure lined with mucosa that forms many longitudinal folds. It functions as a sphincter, separating the caudal reproductive tract from the uterus.

There are essentially three protective barriers in the caudal reproductive tract. The constrictor vulvae muscles of the labia form the first barrier, the second is the vestibular sphincter, and the cervix is the third. When any of these barriers becomes incompetent, contamination of the reproductive tract may occur and result in infertility.

**PATHOPHYSIOLOGY**

Failure of the protective barriers in the caudal reproductive tract can be caused by numerous factors. Mares with conformational abnormalities, such as a flat croup, a sunken anus, or underdeveloped vulvar labia, are predisposed to pneumovagina (Fig. 67-3). Poor perineal conformation is often found in older multiparous mares that are thin in body condition.

A large percentage of the injuries to the caudal reproductive tract occur secondary to trauma from breeding or foaling. Some of the injuries are readily apparent in the immediate postpartum period, but others can go unnoticed until it is time to rebreed the mare. Injuries that occur during foaling include cervical lacerations, cervical contusions, perineal lacerations, rectovestibular fistulas, urinary bladder eversion or prolapse, urinary bladder rupture, vaginal contusions, vaginal lacerations, vestibular lacerations, and uterine...
prolapse or rupture.5-11 The severity of these injuries ranges from minor to severe, and not all require intervention. However, extensive surgical repair may be necessary to restore normal anatomic function. Without repair of the injured tissue, infertility is often the result. When an injury has been identified, a thorough examination is necessary to ensure that more than one anatomic structure does not need surgical repair.

Injuries during breeding do not occur frequently, but they may require medical or surgical treatment.12 When perforation of the vagina occurs (usually during intromission), the lesion is typically located at the cranial aspect of the vagina adjacent to the cervix. Predisposing factors for this type of injury include an overly vigorous stallion or a large stallion breeding a small mare.12 Depending on the location and depth of penetration, the peritoneal cavity may be entered. Semen is not sterile and peritonitis may develop secondary to ejaculation into the peritoneal cavity.13,14 Eventration can occur through a tear in the vaginal wall.15 The development of an abscess in the pelvic cavity may result from an injury that does not involve the peritoneal cavity.16 Inadvertent entry of the stallion’s penis into the mare’s rectum during breeding can result in rectal injury or perforation. This type of accident, which does not occur commonly, has been associated with poor vulvar conformation, a small vulvar opening after a Caslick procedure, and a relaxed anal sphincter after palpation per rectum.12

**Diagnostic Procedures**

Examination of the reproductive tract of the mare should progress from an external to an internal evaluation. Visual evaluation of the conformation of the perineum and vulva as well as looking for evidence of vulvar discharge is a logical starting point. Examination of the external genitalia for diseases such as neoplasia and intersex conditions should be performed. The conformation of the vulva is very important because this anatomic structure is the first line of defense in protecting the reproductive tract from contamination (see Fig. 67-3). The labia should be evaluated for symmetry, position, angle, and tone. Pascoe’s Caslick index is an objective scoring system that can be used to determine the risk for ascending infection to the reproductive tract.9 The length of the vulva (in centimeters) is multiplied by the angle of declination of the vulvar lips. Higher pregnancy rates have been reported in mares that had a Caslick index of less than 150.3

The vestibule, vagina, and cervix should be examined digitally as well as visually, using a speculum. Samples for endometrial biopsy, culture, and cytology should be taken. The reproductive tract should be assessed by palpation and ultrasonography per rectum.

**Chemical Restraint**

The majority of diagnostic and surgical procedures that are performed on the caudal reproductive tract of the mare are accomplished in the standing mare using chemical restraint, usually supplemented with local and/or regional anesthesia for surgical procedures. The drugs used for chemical restraint provide variable degrees of sedation and analgesia. A number of sedative-hypnotic, tranquilizing, and opioid agents are available for use in the horse (see Chapter 20). Selection is based on personal preference and the type of surgical procedure that is being performed. The use of combinations of drugs often optimizes restraint and analgesia as compared with the use of an individual drug.

The use of acetylpromazine, a phenothiazine tranquilizer, produces sedation without analgesia. The peak effect of sedation after intravenous administration (0.04 mg/kg) is approximately 30 minutes, and sedation may last for 1 to 3 hours depending on dosage and route of administration.17 The phenothiazine tranquilizers do not produce analgesia and should be used in combination with an analgesic agent if a surgical procedure is to be performed.

Xylazine and detomidine are the most commonly used sedative-hypnotic drugs for standing chemical restraint. These drugs produce varying degrees of sedation, muscle relaxation, analgesia, and ataxia, depending on the dosage administered. Both drugs induce diuresis, which may warrant placement of a urinary catheter.18 Detomidine has a longer duration of action and greater potency than xylazine.19 Each of these drugs can be used in combination with an opioid such as butorphanol. This typically produces more profound sedation and analgesia. Reduced dosages for chemical restraint should be considered when working on Draft breeds, because they appear to respond more intensely than light breeds.20

**Epidural Anesthesia**

Epidural anesthesia is achieved when the local anesthetic solution is deposited between the dura mater and the periosteum of the spinal canal, which blocks conduction in the caudal nerve roots. The goal of caudal epidural anesthesia is to induce temporary neutralization of sensory innervation while maintaining motor control of the hind limbs. However, the tail should be tied overhead to support the horse in case ataxia develops. The sacrococaudal (first intercoccgeal) vertebral space is selected as the site for injection for epidural anesthesia.21 This location is found by grasping the tail and moving it up and down and palpating...
the first articulation caudal to the sacrum; this is the first intercoccygeal space. The site should be clipped and aseptically prepared. The epidural should be administered using aseptic technique.

Various injection techniques and drug combinations can be used to achieve epidural anesthesia. The mare should be sedated and restrained in stocks during administration of the epidural. A small skin bleb of local anesthetic can be deposited at the proposed injection site to facilitate placement of the spinal needle. A 20-gauge, 7.5-cm spinal needle should be positioned just cranial to the dorsal spinous process of the second coccygeal vertebra. The needle is inserted through the skin at an angle of 30 degrees relative to the tail and advanced cranially. If bone is encountered, the needle should be redirected. Once the needle is placed, the stylet should be withdrawn and the hub of the needle filled with the local anesthetic to be injected. If the needle is positioned in the epidural space, the fluid will be aspirated into the needle (hanging drop technique). Minimal resistance is encountered during epidural injection. Mares that have had previous epidural injections may develop fibrous scar tissue over the intercoccygeal space, making needle placement difficult.21 After the injection, the needle should be removed. Caution should be exercised during placement of the spinal needle, since some mares kick during the procedure. An epidural catheter can be placed to facilitate readministration of anesthetic agents if needed during the surgery.20 Loss of anal sphincter tone is common when epidural anesthesia is achieved.

The type of blockade (motor and/or sensory) and the duration of effect depends on the drug type and the volume that is administered. Local anesthetics produce motor and sensory blockade, whereas only sensory innervation is lost with other drug treatments. The use of 5 to 7 mL of 2% lidocaine hydrochloride per 500 kg of body weight should produce analgesia within 5 to 15 minutes, and the duration of analgesia should be 60 to 90 minutes.22 Two percent mepivacaine hydrochloride given at the same dosage produces analgesia in 10 to 30 minutes and provides analgesia for 90 to 120 minutes.21 Ataxia is a complication when using local anesthetics.

Epidural administration of α2-adrenergic agonists such as xylazine provides profound analgesia without the complication of ataxia.22,23 The recommended dosage of xylazine is 0.17 mg/kg. The onset of action is 10 to 30 minutes, and the duration of analgesia is 2½ to 4 hours.22 The xylazine should be diluted in saline to a total volume of 6 to 10 mL. Epidural administration of detomidine (30 to 60 µg/kg) provides analgesia lasting for 2 to 3 hours but produces sedation and ataxia.22,23 The combination of lidocaine (0.22 mg/kg) and xylazine (0.17 mg/kg) produces significantly longer analgesia (approximately 5 hours) with only mild ataxia when compared with lidocaine used alone.23

Preparation of the Surgical Site and the Mare

The rectum should be evacuated prior to starting any surgical procedure on the caudal reproductive tract. The tail should be wrapped and secured so that it does not interfere during surgery. The perineum and buttocks should be scrubbed with a nonirritating soap. A dilute antibacterial solution of 1% Betadine can be used to cleanse the vestibule and vagina. All fluid should be removed from the vestibule and vagina before beginning surgery.

Tetanus prophylaxis should be administered if necessary. The use of perioperative antibiotics and anti-inflammatory drugs is at the discretion of the surgeon.

Instrumentation

Special instruments are needed to perform certain surgical procedures on the caudal reproductive tract. Illumination of the surgical field is crucial. Options include a light source that can be attached to the self-retaining retractor, a headlamp, or overhead surgical lights that can be adjusted. Retractors are needed to provide exposure to the surgical site. A modified Finochietto retractor with long blades (Sontec Instruments, Englewood, Colo) (Fig. 67-4) is very helpful in repairing cervical lacerations. Balfour retractors are useful for surgical procedures caudal to the vestibulovaginal junction. Positioning the retractor with the retaining mechanism so that it is dorsal to the anus, and securing it to the tail head using umbilical tape keeps the retractor in place and out of the surgical field. Hand-held instruments need to be longer than conventional instruments (Fig. 67-5). Scalpel handles, scissors, thumb forceps, Allis tissue forceps, and needle holders should be 25 to 30 cm in length.24

DISORDERS REQUIRING SURGERY

Pneumovagina

Pneumovagina leads to chronic inflammation and infection of the vagina and uterus and is one cause of infertility in the mare. The most common cause of aspiration of air into the vagina is poor perineal conformation (see Fig. 67-3). Pneumovagina may develop secondary to foaling trauma with scar tissue formation, excessive stretching of the vulvar tissues from foaling, or poor body condition.8 Sinking of the anus into the pelvic canal causes the dorsal commissure of
the vulva to tip forward and have a horizontal orientation as opposed to vertical. This can disrupt the vulvar seal and lead to pneumovagina as well as fecal contamination of the caudal reproductive tract. If manually separating the labia results in an inrushing of air, the mare is predisposed to pneumovagina. In some mares, pneumovagina occurs only during estrus when perineal tissues are more relaxed. Urovagina can result from the same causes as pneumovagina, and the mare should be evaluated to determine if more than one surgical procedure is necessary.

**Episioplasty**

**CASLICK PROCEDURE**

The most common surgical method for correction of pneumovagina is the Caslick procedure, first described in 1937. The intent of this surgery is to form a seal to prevent aspiration of air or fecal material into the vestibule. This is accomplished by incising the labia or excising a thin strip of tissue from the labial borders and then suturing the labia together. Pneumovagina can be prevented in most cases by suturing the labia together to the level of the ventral border of the ischial arch. The ventral limit is determined by palpating the ischial arch just lateral to the opening of the vulva. The mare should be sedated and restrained so that the clinician is protected from a kick injury. The perineum is prepared, and local anesthesia is infiltrated into the labial margins extending from the ischial arch to the dorsal commissure. A 4- to 8-mm-wide strip of mucosa is excised with a pair of scissors along the mucocutaneous junction on each labium (Fig. 67-6). It is important to include the dorsal commissure of the vulva in the excision, so that a seal at the dorsal aspect is achieved. Alternatively, a scalpel can be used to incise the labia at the mucocutaneous junction rather than to excise any tissue. The incision must be of sufficient depth so that a tissue gap of 4 to 8 mm is achieved.

Closure is achieved using 2-0 absorbable or nonabsorbable suture material in a continuous pattern. Stainless steel skin staples can be used for the closure instead of suture material. The sutures or staples should be removed 10 to 12 days later, and the surgery site should be evaluated for fistula formation. Because fistula formation can lead to aspiration of air and fecal material and negate the effects of the procedure, it should be repaired.

A mare requiring a Caslick procedure will very likely continue to need the procedure done for the rest of her broodmare life, so care should be taken to remove only as much tissue as necessary to achieve a complete seal between the labia. Excessive removal of tissue will make subsequent Caslick procedures more difficult because of fibrosis and loss of tissue. Older mares that have had numerous Caslick procedures occasionally develop enough fibrous tissue or lose enough skin to make closure difficult as a result of tension. This may lead to dehiscence of a routine Caslick procedure. In such cases, a three-layer closure can be used. The inner layer consists of the mucosa of the two labia, which is apposed using 2-0 absorbable suture material in a continuous horizontal mattress pattern. Then, the constrictor vulvae muscles are apposed using 2-0 absorbable suture material in a similar pattern. Finally, the cutaneous layer is apposed using 2-0 or 0 absorbable or nonabsorbable suture material in a continuous pattern.

A breeding stitch is often placed at the ventral limits of the suture line to protect the Caslick procedure at subsequent breeding. This consists of an interrupted suture of small-width umbilical tape or large-diameter suture material that is placed 2 to 3 cm lateral to both sides of the mucocutaneous border of the labia (Fig. 67-7). The suture must be positioned so that it does not interfere with the stallion’s penis during intromission. Natural cover of the mare can be achieved with the suture in place by manually elevating the vulvar opening and guiding the stallion’s penis. The breeding stitch is removed once the mare is confirmed to be pregnant.
Urovagina may result from excessive closure of the vulvar cleft.\textsuperscript{29} Closure is considered excessive if a tube speculum cannot be readily passed.\textsuperscript{28} Some mares have such poor perineal conformation that performing a Caslick procedure predisposes them to urovagina. In such cases, an alternative surgical procedure to correct the pneumovagina or a procedure to correct urovagina is necessary (see later).

In mares that have had a Caslick procedure, an episiotomy should be performed 2 weeks prior to foaling to prevent damage to the vulva and perineum during the foaling process.

PERINEAL BODY RECONSTRUCTION

Reconstruction of the perineal body is useful when the vulvar and vestibular constrictor muscles have become ineffective.\textsuperscript{25} Damage to the perineal body occurs from repeated stretching of these muscles in older multiparous mares, or from foaling trauma (second-degree rectovestibular injury). The goal of this surgery is restoration of the integrity of the dorsal aspect of the vestibule and return of vestibular sphincter function. The surgical procedure is termed an episioplasty, the Gadd technique, or perineal body reconstruction.\textsuperscript{30}

The surgery is performed with the mare sedated and restrained in stocks. Epidural anesthesia or local infiltration is used to desensitize the surgery site. The labia are retracted to the side using towel clamps or stay sutures. An incision is made along the mucocutaneous junction of the labia in a dorsoventral direction and extending cranially along the dorsal commissure of the vestibule to the level of the vestibulo-vaginal sphincter. Dissection is continued submucosally from the dorsal and dorsolateral aspects of the vestibule. The triangular tissue flaps of mucosa are excised, and this approximates the shape of the perineal body. Using caudal dorsal retraction on the stay sutures, a position for closure of the tissues is chosen so that the vulva will have a more vertical orientation after the procedure is completed (Fig. 67-8).

Closure of the tissue layers begins with closure of the vestibular mucosa using 2-0 or 0 absorbable suture material in a horizontal mattress pattern, inverting the mucosa into the vestibule. The submucosal tissue is closed beginning at the cranial aspect of the vestibule using No. 0 or 1 absorbable suture material in an interrupted pattern. The labial skin is apposed as for the Caslick procedure. Four weeks of sexual rest is recommended after surgery. Since the diameter of the vestibule has been decreased by this procedure, some mares require an episiotomy at the time of foaling.\textsuperscript{31}

PERINEAL BODY TRANSECTION

This technique is used to treat both pneumovagina and urovagina by the separation of muscular and ligamentous attachments between the rectum and the caudal reproductive tract.\textsuperscript{32} The objective of this surgery is to return the vulva to a more natural conformation. The mare is sedated and restrained in stocks and epidural anesthesia or local infiltration of the perineal body is performed. A 4- to 6-cm horizontal skin incision is made midway between the ventral aspect of the anus and the dorsal commissure of the vulva. This incision is continued ventrad for 3 to 4 cm on both sides of the vulva. A combination of blunt and sharp dissection is utilized to extend the dissection in a cranial direction through the muscles of the perineal body. The dissection is continued cranially for 8 to 14 cm until the
connections between the rectum and caudal reproductive tract have been severed.30 Placing a hand in the vestibule to help guide the dissection helps prevent inadvertent entry into the rectum or peritoneal cavity. The dissection should be continued until the vulva has attained a normal vertical position without applying traction (Fig. 67-9). No attempt is made to close the resulting dead space between the rectum and reproductive tract. Closure of the skin, either transversely or in a T-shaped configuration, has been suggested.32,33 An alternative involves allowing the wound to heal by secondary intention, which should occur within 3 weeks.25 Natural cover should be delayed until the surgery site has healed (3 weeks). Mares may be bred by artificial insemination immediately.

Urovagina

Vesicovaginal reflux is the accumulation or pooling of urine in the vaginal fornix of the mare.29 Urovagina and urine pooling are terms that have also been used to describe this condition. This abnormality is most often seen in thin, multiparous mares in which the cranial vagina slopes ventrally. Stretching and relaxation of the supporting ligaments of the urogenital tract lead to the excessive cranioventral sloping of the vagina. Mares often have a sunken appearance to their anus and dorsal vulva and frequently have had a Caslick procedure performed.34 Excessive closure of the dorsal vulva during a Caslick procedure may contribute to urine reflux by causing back-splash of urine into the vagina.35 In young fillies that are experiencing urovagina, an ectopic ureter must be ruled out.29

The chronic presence of urine in the cranial vagina leads to vaginitis, cervicitis, and endometritis. These inflammatory conditions can interfere with the ability of the mare to conceive and carry a foal to term.36 Urovagina is diagnosed by finding an accumulation of urine in the fornix of the vagina during vaginoscopy. It is best to perform a speculum examination of the vagina during estrus, because some mares pool urine only when the reproductive tract is under the influence of increased circulating levels of estrogen.29 Examination of the mare on several occasions and finding urine in the cranial aspect of the vagina confirms the diagnosis. The differential diagnosis of urine pooling should include uterine infection with accumulation of exudate in the cranial vagina. Evaluation of the accumulated fluid using laboratory tests and cytology is often necessary. A cytologic evaluation of the fluid involves checking for bacteria, white blood cells, and calcium carbonate crystals. Creatinine and urea nitrogen testing can be performed on the fluid. Creatinine levels in accumulated urine can be expected to be at least two to three times serum creatinine levels.29

Surgical intervention is usually required for treatment of urine pooling.35,37-39 Mares with poor body condition and the resulting abnormal perineal conformation can benefit from weight gain. Manual evacuation of urine from the cranial aspect of the uterus with a speculum may improve conception rates, but this does not address the long-term negative side effects of urovagina. Definitive surgical treatment for vesicovaginal reflux involves modification of the external urethral orifice.

Caudal Relocation of the Transverse Fold

Caudal relocation of the transverse urethral fold was first described in 1972 by Monin. The Monin technique is beneficial only when the reflux and abnormal perineal conformation are minimal.29,39 This procedure does not resolve severe vesicovaginal reflux and can make subsequent surgical procedures such as a urethral extension more difficult.

A Balfour retractor or stay sutures are utilized to provide access to the transverse fold of the external urethral orifice. The center of the fold is grasped with an Allis tissue forceps and retracted caudally toward the surgeon (Fig. 67-10). The transverse fold is incised in a horizontal plane, splitting it into dorsal and ventral shelves. Thumb forceps are used to
position the transverse fold along the ventrolateral walls of the vestibule. Mucosal incisions are then made in the walls of the vestibule at the proposed site of attachment. The transverse urethral fold is sutured to the vestibular floor in the retracted position, creating the extension. A one- or two-layer closure may be performed using 2-0 absorbable suture material. This technique creates a urethral orifice that opens 2.5 to 5 cm more caudally after completion of the procedure. It is important to position the transverse fold so that it is not placed under excessive tension. This technique is simple to perform but it has the disadvantage of not being able to extend the urethral opening as far caudally as other urethral extension procedures.

Urethral Extension

Several urethral extension procedures have been described, and all have the advantage of being able to extend the urethral opening as far caudally as necessary. A common pitfall of urethral extension procedures is fistula formation along the suture line. In most instances, fistula formation must be repaired. However, the surgeon should wait until tissue inflammation has subsided before attempting another repair (Fig. 67-11).

The mare should be sedated and restrained in stocks, and epidural anesthesia should be administered to desensitize the perineum. Balfour retractor or stay sutures can be used to provide access to the surgical site. When self-retaining retractors are used, excessive lateral retraction should be avoided because this makes apposition of the vestibular mucosa more difficult. Insertion of a no. 30 French Foley catheter into the bladder ensures an adequate lumen diameter of the urethral extension and helps prevent urine contamination of the surgery site.

**BROWN TECHNIQUE**

The first urethral extension procedure, described in 1978, involves creating tissue flaps beginning at the level of the transverse urethral fold and continuing to just inside the labia. The free edge of the transverse urethral fold is incised with a scalpel in a horizontal plane, creating dorsal and ventral tissue flaps of equal thickness (Fig. 67-12). It is important not to create holes in the flaps during the dissection. The transverse incision is continued caudally along the vestibular wall to create a dorsal and ventral shelf of vestibular mucosa and submucosa. Dissection dorsally and ventrally allows the flaps to be apposed on the midline without any tension. It is critical that the dissection generate tissue flaps large enough to result in a urethral tunnel of adequate diameter. The ventral shelves of tissue from opposing sites are sutured using 2-0 absorbable material in a continuous horizontal mattress pattern that inverts the mucosa of the ventral shelf into the new urethral lumen. The submucosa is closed using 2-0 absorbable suture material in a continuous...
pattern. The dorsal shelves are sutured using 2-0 absorbable suture material in a continuous horizontal mattress pattern that everts the mucosa into the vestibule. In the original description, urine pooling was resolved in 16 of 18 mares.35 After surgery, 11 mares were bred and 7 of them conceived.35

SHIRES TECHNIQUE
The Shires technique also creates a urethral tunnel using mucosa from the floor of the vestibule around a Foley catheter placed in the bladder.38 A No. 30 French Foley catheter is inserted through the urethral orifice into the bladder, and the balloon is inflated to secure the catheter (Fig. 67-13). Interrupted horizontal mattress sutures using 2-0 or 0 absorbable suture material are placed in the ventral vestibular mucosa and tied so that a tunnel is formed over the catheter. The sutures must be positioned so that there is minimal tension on the mucosa over the catheter. The tunnel must begin cranial to the urethral orifice and extend caudally to a point approximately 2 to 3 cm cranial to the vulva. The everted ridges of mucosa dorsal to the horizontal mattress sutures are excised using a scissors after the completion of the tunnel. The cut edges of the mucosa are apposed using 2-0 absorbable suture material in a continuous pattern. This procedure is relatively easy to perform and has been reported to be successful after a single surgery in 12 of 15 mares.38
Shires technique for urethral extension. A, Vestibular mucosa is apposed over a Foley catheter using horizontal mattress sutures. B, The everted mucosal ridge is excised. C, The exposed submucosa is apposed using a continuous suture pattern.

MCKINNON TECHNIQUE
The McKinnon technique, described in 1988, results in a larger and stronger urethral tunnel than obtained by the Brown and Shires techniques. A horizontal incision is made in the mucosa of the transverse fold of the urethra 2 cm cranial to the caudal free edge (Fig. 67-14). Incisions are made in the lateral walls of the vestibule approximately one-half the distance from the floor of the vestibule. Dissection of the tissue flaps continues in a ventral direction until the flaps can be apposed on midline without tension. The tissue flaps are sutured using a one-layer technique of 2-0 absorbable suture material in a continuous horizontal mattress pattern, inverting the mucosa into the lumen of the urethral tunnel. The initial dissection over the transverse urethral fold results in the cranial aspect of the closure assuming a Y-shaped pattern before the two suture lines meet on midline. Correction of urovagina using this technique was achieved in 32 of 34 mares, with fistula formation occurring in 5 of 34 mares. Fistula formation is most common at the junction of the Y-suture pattern. The exposed submucosal tissue heals by secondary intention. Mares may be bred 1 month postoperatively.

COMBINED MCKINNON AND BROWN TECHNIQUE
Combining the McKinnon and Brown techniques for urethral extension has been reported. The initial dissection is similar to that in the Brown technique. The caudal free edge of the transverse fold of the urethral orifice is incised into dorsal and ventral shelves of equal thickness (Fig. 67-15, A and B). It is important that no holes be created in these tissue layers during dissection. The incisions are continued caudally along the ventrolateral walls of the vestibule to a point approximately 2 cm cranial to the labia. Submucosal dissection is performed to create dorsal and ventral vestibular tissue flaps that can be apposed on midline and create a urethral lumen of adequate diameter. A no. 30 French Foley catheter can be inserted into the bladder to help determine the location of the incisions and prevent urine contamination of the surgical field (see Fig. 67-15, C). The dissection of the vestibular walls is not as dorsal as described for the McKinnon technique.

Closure of the tissue flaps is performed as follows. The midpoint of the caudal free edge of the transverse urethral fold is grasped with an Allis tissue forceps and retracted caudally (see Fig. 67-15, D). Suturing begins at the junction of the right ventral flap of the transverse fold and the right ventral flap of the vestibular wall. A continuous horizontal mattress pattern using 2-0 absorbable suture material is used (see Fig. 67-15, D). The mucosa of the ventral flaps should be inverted into the lumen of the urethral extension. During closure, it is important to retract the transverse fold caudally. This suture pattern is continued caudally to the midpoint of the transverse fold, and the suture is tied. The right dorsal flap of the transverse fold and the right dorsal flap of the vestibular wall are sutured next, using a continuous horizontal mattress pattern of 2-0 absorbable suture material that everts the mucosa into the vestibule (see Fig. 67-15, E [a]). The procedure is repeated for the left side. The remainder of the roof of the urethral tunnel is created by first suturing the right and left ventral vestibular tissue flaps and then the dorsal flaps. The ventral flaps are apposed using 2-0 absorbable suture material in a continuous horizontal mattress pattern, inverting the mucosa into the urethral lumen (see Fig. 67-15, E [a]). The dorsal flaps are apposed using continuous horizontal mattress pattern, evert the mucosa into the vestibular lumen (see Fig. 67-15, E [c]). The most difficult part of the repair is at the junction of the Y of the three tissue layers— transverse urethral fold and right and left vestibular tissue flaps. This location is most prone to dehiscence and fistula formation. Therefore, a third layer of sutures using 2-0 absorbable suture material placed in a simple-continuous everting pattern around the circumference of the Y is used as shown in Figure 67-15, E (b). Maintaining a urinary catheter postoperatively for some time is based on surgeon preference (see Fig. 67-15, F and G).

Foaling Injuries
Numerous types of injuries may be associated with parturition in the mare. Injuries caused by foaling and the resulting complications make up a large percentage of injuries to the perineum and cervix. Most injuries are obvious after foaling, but some are not apparent until it is time to rebreed the mare.

Perineal Lacerations
Perineal lacerations typically occur during unassisted foaling, most commonly in primiparous mares. These injuries are most likely caused by the prominence of the vestibulovaginal sphincter and remnants of the hymen in mares foaling for the first time. It is hypothesized that the forefoot of the foal catches on the dorsal transverse fold of the vestibulovaginal junction, and the mare's abdominal press forces the foal's foot into the roof of the vestibule. Perineal lacerations have been classified into first-, second-, and third-degree lacerations, based on the extent and severity of the injury. First-degree perineal lacerations involve the mucosa of the vestibule and the skin of the dorsal commissure of the vulva. Second-degree perineal lacerations involve vestibular mucosa and submucosa and continue into the muscles of the perineal body, including the constrictor vulvae muscle. These injuries do not involve the anal sphincter or rectum. However, when the foal's foot penetrates the vestibule and enters the mare's rectum, a rectovestibular fistula results if a
Figure 67-15. A, The scalpel is used to split the free edge of the transverse fold into dorsal and ventral shelves. B and C, Dorsal and ventral mucosal shelves are created by undermining the vestibular mucosa. The dissection should allow the shelves to meet on the midline without tension. D, The midpoint of the horizontal shelf is retracted caudally, and the ventral shelf is closed using a continuous horizontal mattress pattern to invert the tissue into the newly created urethral tunnel in a Y pattern. E, (a) The dorsal shelves are sutured using a continuous horizontal mattress pattern to evert the tissue into the vestibule. (b) An additional continuous everting suture is placed around the three portions of the Y and tied at the end to provide further support to this very vulnerable location. (c) Close-up view of the new urethral shelf with the two everting patterns. F, The completed urethral extension. G, A clinical case showing the urinary catheter in place.
A foaling attendant is present to replace the foal’s foot back into the vestibule or if the foal retracts its foot; otherwise, a third-degree perineal laceration ensues as foaling continues with the foot in the rectum.

First-degree injuries typically do not require surgical intervention. If needed, a Caslick procedure can be performed. Repair of second-degree injuries requires a Caslick procedure and reconstruction of the perineal body. The mare will develop a sunken perineum and be predisposed to pneumovagina and urovagina if the perineal body is not reconstructed.

All third-degree perineal lacerations require surgical repair. The management is divided into two parts: immediate treatment and delayed surgical repair. Repair of a third-degree perineal laceration in the acute stage should not be attempted. The tissue is very edematous and contaminated with feces, and some tissues may not be viable (Fig. 67-17). Repair should be delayed at least 3 to 4 weeks, or longer if possible, to allow healing of the injured tissues (Fig. 67-18). Initial therapy should include daily wound care and cleaning of the contaminated tissues. Third-degree perineal lacerations result in continuous bacterial contamination of the vagina and uterus. However, the inflammatory uterine changes are reversible after surgical repair. A uterine biopsy is not needed because preoperative uterine biopsy grades do not correlate with conception data after surgery.

Initially, dietary changes may be necessary so that the mare has soft feces without an excessive amount of water content, to limit uterine contamination. Many methods can be used to soften the feces. Pasturing the mare on lush green grass, administering laxatives such as mineral oil or magnesium sulfate via a nasogastric tube, and feeding wet bran mashes are a few examples. Additional dietary changes should be instituted well before surgery so the fecal consistency is soft by the date of surgery. If the mare has formed feces, the surgery should be postponed because dehiscence of the surgical repair is likely. Often, the surgery is delayed until the foal is weaned, so that the foal does not have to enter the hospital environment. However, the timing of the surgery may be dictated by the urgency to get the injury repaired and the mare rebred.

Surgery is performed with the mare sedated and restrained in stocks. The use of epidural anesthesia is necessary. After surgery, soft fecal consistency should be maintained for at least 2 to 3 weeks.

**TWO-STAGE REPAIR**

The Aanes technique or a two-stage repair is designed to minimize obstipation, which can lead to failure of the repair. In the first stage of the repair, the rectovestibular shelf is reconstructed without repair of the perineal body. Three to 4 weeks later, the second stage, or perineal body repair, is performed.

Balfour retractors or stay sutures can be used to provide access to the surgical site. Initial dissection begins cranially in a frontal plane at the level of the rectovestibular shelf.
Figure 67-18. Third-degree perineal laceration ready for repair. The rectal mucosa overhangs the intact shelf at the cranial extent of the laceration. Arrows point to the junction of the rectal mucosa and the vestibular mucosa.

Thumb forceps can be used to place tension on the recto-vestibular shelf to facilitate dissection. A combination of sharp and blunt dissection is used to divide the tissue into rectal and vestibular shelves (Fig. 67-19). The rectal shelf should make up two thirds of the thickness, and the vestibular shelf one third. The plane of dissection is continued cranially for a distance of 3 to 5 cm. The cranial dissection is important to relieve tension at the tissue edges. The incisions are continued laterally and caudally through the scar tissue that has formed at the junction of the rectal mucosa and the vestibular mucosa. The dissection is continued laterally until the tissue shelves can be apposed on the midline without tension. Hemostasis using ligatures can be performed if necessary. Once sufficient dissection has been achieved, reconstruction of the tissue shelves can commence.

The first stage of the repair is composed of two suture lines. The first suture line apposes the vestibular shelves. A continuous horizontal mattress pattern of no. 1 or 2 absorbable suture material is used to invert the vestibular mucosa into the vestibule. The second suture line is placed at the cranial edge of the dissected shelf and follows this sequence:

1. The first bite is deep in the left vestibular flap in a ventral-to-dorsal direction.
2. The second bite is in the left rectal submucosa, taking care not to penetrate the rectal mucosa.
3. The third bite is in the right rectal submucosa.
4. The fourth bite is through the right vestibular flap in a dorsal-to-ventral direction.
5. The fifth bite re-enters the right vestibular shelf axial to the fourth bite in a ventral-to-dorsal direction.
6. The sixth bite is in the left vestibular flap from dorsal to ventral and is positioned axial to the first bite.

When the suture is tied, the rectal edges should be apposed and the vestibular edges should be everted into the lumen of the vestibule. The sutures should be placed approximately 1.5 cm apart. Any sutures that are loose or placed too far apart should be replaced; failure to do so will compromise the repair. Closure of the rectal mucosa has been proposed but is not necessary.41 This repair is continued to a point approximately 4 to 6 cm cranial to the cutaneous perineum. At this point, the perineal body is repaired as previously described. A Caslick operation is performed if necessary.

The single-stage repair can be performed using the Aanes reconstruction technique as described for the two-stage repair. Another modification of the single-stage repair uses a three-layer closure that includes a continuous horizontal mattress suture in the vestibular submucosa and rectal submucosa, inverting each mucosa into its respective lumen.44 Simple-interrupted sutures are placed in the connective tissue shelf between the rectum and vestibule. All three sutures are started cranially and continue in an alternating fashion toward the vulva.

B, The junction between the rectal mucosa and the vestibular mucosa is delineated by a thin line of scar tissue. C, Vestibular and rectal tissue flaps are created by dissecting along the line of scar tissue. D, The vestibular mucosa is inverted into the vestibule using a continuous horizontal mattress pattern. The submucosal tissues are apposed using an interrupted pattern. E, Completed first-stage repair.
Rectovestibular Fistula

Rectovestibular fistula formation is the result of a perineal laceration from the dorsum of the vestibule into the rectum, without disruption of the anal sphincter (Fig. 67-22). These fistulas can form secondary to an unsuccessful repair of a third-degree rectovestibular laceration. Small fistulas sometimes close with conservative therapy, but larger ones require surgical repair.40 Fistulas are most commonly 3 to 5 cm in diameter and located cranial to the perineal body.43 Surgical approaches include conversion of the fistula into a third-degree perineal laceration, a horizontal approach through the perineal body, and a direct suturing technique.

A horizontal skin incision is made midway between the ventral aspect of the anus and the dorsal commissure of the vulva (Figs. 67-23 and 67-24, A). A combination of blunt and sharp dissection is used to separate the perineal body. This plane of dissection is continued through the fistula for a distance of 3 cm. Stay sutures or Allis tissue forceps can be used to help retract the tissue during dissection. It is important not to penetrate into the rectum or vestibule before reaching the fistula. The dissection should be such that the rectal shelf of tissue is thicker (two thirds of the thickness) than the vestibular shelf (one third of the thick-
ness). The fistula in the rectal tissue is closed transversely using an interrupted Lembert pattern of no. 0 absorbable suture material. The fistula in the vestibular shelf is closed longitudinally in a continuous horizontal mattress pattern. This results in the suture lines being oriented at right angles to one another (see Fig. 67-24, C). The dead space created by the approach is closed using interrupted pursestring sutures. The skin is closed with a continuous or an interrupted pattern. An alternative is to allow the dead space and skin to heal by secondary intention.11

Direct suturing techniques have been described for successful repair of rectovestibular fistulas.45,46 Recently, a mucosal pedicle flap technique for repair of rectovestibular fistulas was described.47 This technique is performed as a standing procedure. The edges of the fistula are débrided by full-thickness excision of 2 mm of the margin of the fistula. The fistula dimensions are assessed and a dorsally based U-shaped mucosal and submucosal pedicle flap is dissected from the vestibular wall. The flap is rotated 90 degrees so

that the vestibular mucosa is continuous with the rectal mucosa covering the fistula. The flap is sutured in place using absorbable suture material placed in an interrupted pattern. Two of the three horses treated with this technique healed by primary intention. The third horse required additional sutures to repair a partial dehiscence.47

Cervical Injuries
Injuries to the cervix usually occur during foaling. They result from stretching, tears, and lacerations and have significant adverse effects on fertility. Cervical injuries can be placed into three categories related to their repair: lacerations, adhesions, and incompetence.

Lacerations
Lacerations of the cervix occur during foaling, as a result of excessive stretching until the musculature tears, often along with the mucosa. Cervical injury is more likely to develop during dystocia or in association with a fetotomy.48 Cervical lacerations have been reported to occur during normal parturition and during the abortion of a relatively small fetus.24 Cervical laceration of the cervix has also been reported following breeding.24 The incidence of cervical lacerations is reported to be higher when parturition is induced.42 This may be the result of the cervix not relaxing adequately prior to foaling.

The most common clinical signs associated with cervical lacerations are failure to conceive, endometritis, early fetal abortion, and persistent infertility. All mares that have undergone dystocia should have their cervix examined approximately 21 days postpartum49 (Fig. 67-25). Palpation of the cervix is crucial to making a diagnosis of a cervical laceration. Lacerations can be easily missed on visual examination alone, because the mucosa will have healed over the lacerated or separated musculature of the cervix. Lacerations can even be missed on palpation, especially if the mare is near estrus and has a relaxed cervix. Therefore, diestrus is the optimal time to evaluate the cervix. During this stage of the reproductive cycle, the cervix should be constricted in size, which allows an accurate determination of cervical continuity.

The cervix is evaluated in the following manner. The perineum should be washed and prepared for examination. The examiner should wear a sterile glove or sleeve and apply an ample amount of lubricating jelly. The hand is inserted into the vagina of the mare and the cervix is identified at the most cranial aspect of the vaginal fornix. When using the right hand to examine the cervix, the examiner places the thumb in the lumen of the cervix and uses the index finger to palpate the cervix from the most dorsal aspect to the most ventral aspect of the right side of the cervix. To examine the left side of the cervix, the examiner inserts the index finger into the lumen and uses the thumb to palpate the cervix from the most dorsal to the most ventral aspect of the left side of the cervix. If a cervical laceration is present, the severity and extent should be determined. Not all cervical lacerations require surgical repair. It has been reported that surgery is unnecessary if 50% or less of the vaginal cervix is involved.50 However, the economic impact of fetal loss must be considered, and if it is possible to improve the chances that a mare will conceive and carry the foal to term, surgical intervention is warranted.

Surgery should be performed during diestrus and at least 3 weeks postpartum. Alternatively, the repair can be performed immediately after the mare is bred (just after ovulation). The mare is sedated and restrained in stocks, and epidural anesthesia is used. A modified Finochietto retractor with long blades (Sonpec Instruments) is very helpful in repairing cervical lacerations. Surgical interventions on the cervix should be performed in a caudally retracted position to bring it closer to the surgeon. Methods for retracting the cervix include Knowles cervical forceps and stay sutures (Fig. 67-26). The Knowles cervical forceps are more traumatic than stay sutures and are not necessary. Three stay sutures using large-diameter (no. 2) suture material are placed in the external cervical os by hand or with the aid of long needle holders. The stay sutures must be positioned to accentuate the cervical defect and so as not to interfere with

Figure 67-25. A dorsal cervical laceration as seen at speculum examination. Not all cervical lacerations are visible.

Figure 67-26. Stay sutures are used to retract the cervix into the vestibule to facilitate repair. The sutures are placed to accentuate the defect in the cervix. The arrow points to the defect.
the dissection and repair of the defect. The long ends of the stay sutures should be tagged with a hemostat and the needle removed. An assistant should apply gentle, steady caudal traction on the stay sutures so that the surgeon has access to the cervix. The cervix can usually be retracted to the level of the vestibulovaginal junction. Allis tissue forceps are used to grasp the caudal-most extent of the scar tissue on each side of the cervical laceration. The scar tissue is excised using a scalpel blade or a scissors. Following excision of the scar tissue, the three layers of cervical tissue should be evident.

Repair of the defect is accomplished by a three-layer closure. The first layer, the inner cervical mucosa, is the most difficult to close and probably the most important. This layer is closed using no. 0 or 1 absorbable suture material in a continuous horizontal mattress pattern to invert the mucosa into the cervical lumen, beginning at the most cranial aspect of the defect and working caudally. After each bite, the surgeon should check whether the cervical lumen was penetrated and to ensure the patency of the cervical lumen. The second layer in the cervical muscle is apposed using no. 1 absorbable suture material placed in a simple-continuous pattern. The third layer, the outer cervical mucosa, is closed using no. 1 absorbable suture material placed in a simple-continuous pattern. In a report of 53 mares, a 75% pregnancy rate was achieved after surgical repair of cervical lacerations.51 The mare should not be bred for at least 30 to 45 days after surgery, unless breeding was completed just before repair.

Adhesions

Transluminal adhesions interfere with the normal opening and closing of the cervix.49 Less severe adhesions may lead to infertility, whereas more severe adhesions can result in mucemetric or pyometra.55 Adhesions may form secondary to cervical trauma or cervical laceration repair. The more extensive the adhesions, the worse is the prognosis. Transluminal adhesions can be broken down manually or surgically. Daily topical application of steroid-based ointment to the cervical lumen has been recommended as a means of preventing the adhesions from re-forming.16 Adhesions from the vaginal wall to the cervical os can be relieved by sharp and blunt dissection. The surgeon must be careful not to perforate the vaginal wall and enter the peritoneal cavity when working in the cranial aspect of the vagina.

Incompetence

Incompetence of the cervix can result from a tear that cannot be effectively repaired, it can result from muscle atony from repeated stretching, or it may be a congenital anomaly.16,52,53 Mares with an incompetent cervix may fail to conceive or experience early fetal abortion. Correction of these cervical problems has met with varied success.16 The use of a buried retention suture or a nonabsorbable suture used in purse-string fashion around the base of the external os has been described.54 The authors recommended that the suture be placed during the first 48 hours after breeding and ovulation. The suture must be removed prior to foaling. The success of this type of procedure is not known.

Clitoral Disorders

Abnormal conditions of the clitoris are rare. Squamous cell carcinoma has been reported to affect the clitoris.55 Smegma can become impacted in the clitoral sinuses.56 The sinuses of the clitoris can harbor *Taylorella equigenitalis*, the causative agent of contagious equine metritis (CEM).57

Extrirpation of the clitoral sinuses has been recommended as a treatment of mares affected by CEM. Sinulectomy is completed as a standing procedure using local anesthesia. The glans clitoridis is not excised. The frenulum clitoridis, which is a fold of tissue overlying the clitoral sinuses, is retracted dorsally, and submucosal dissection is used to remove all clitoral sinus mucosa.57 The resulting surgical wounds are left open to heal by secondary intention.

Congenital Anomalies

Congenital anomalies do not occur very often. Persistent hymen is the most frequently observed developmental anomaly of the mare’s tubular genital system58 (Fig. 67-27). The hymen may be imperforate or may be persistent in varying degrees because of failure of the caudal sections of the mullerian duct to fuse with the urogenital sinus. Failure of proper fusion of the mullerian ducts may result in a dorsoventral band in the cranial aspect of the vagina coursing across the external os of the cervix.59 Surgical removal easily resolves both of these problems.

Developmental anomalies of the cranial vagina, cervix, and uterus are the result of partial or complete inhibition of mullerian ducts. These anomalies are rare but occur more frequently in the cervix than in the vagina or uterus. Reports of congenital cervical anomalies include cervical aplasia,
REPRODUCTIVE SYSTEM

double cervix, and congenitally incompetent cervix.52,53 Segmental aplasia of portions of the reproductive tract are rarely seen and may be associated with mucometra.16 Ovariohysterectomy is recommended as a salvage procedure.

Incomplete separation of the urorectal septum leads to the formation of a rectovestibular fistula.60 This is often seen in conjunction with atresia ani. In addition to urogenital abnormalities, other anomalies may be present. Atresia ani may be a heritable condition in the horse; therefore, salvage of affected foals for breeding purposes is not advised.

OVARIES AND UTERUS

CHAPTER 68

Ovaries and Uterus

Rolf M. Embertson

ANATOMY
The ovaries in the mare are about 70 to 80 mm long and 40 to 60 mm wide, but the size varies depending on the season and stage of the estrous cycle.1 The ovaries are generally kidney shaped, with a palpable indentation representing the ovulation fossa. The cranial aspect of the broad ligament, which contains the ovarian blood supply, the ovarian branch of the ovarian artery, suspends the ovaries.1

The funnel-shaped infundibulum of the oviduct is positioned adjacent to the ovulation fossa of the ovary. The oviduct (uterine tube) becomes very tortuous as it courses to the tip of the uterine horn, where it enters the uterus at the tubal papilla.1

The uterine horns, which lie entirely within the abdominal cavity, extend caudally to the uterine body. Part of the uterine body is positioned in the peritoneal cavity and part is retroperitoneal. The uterine body ends caudally as the thick-walled muscular cervix, which projects into the cranial vagina. The uterus is suspended in the caudal abdomen by the broad ligament, which contains vessels, nerves, lymphatics, fat, connective tissue, and some smooth muscle. It receives its blood supply via the uterine branch of the vaginal artery, the vaginal artery, and the uterine branch of the ovarian artery.1

DIAGNOSTIC PROCEDURES
Advanced diagnostic procedures used to evaluate the cranial reproductive tract of the mare have improved the general understanding of the potential disease processes involved. Competence with these procedures, particularly ultrasonography and endoscopy, has permitted more rapid and accurate diagnoses, yielding more successful treatment regimens. Despite the benefit gained from these technologies, a complete history and a thorough physical examination are still the foundation of the diagnostic workup. Palpation often provides as much, if not more, information than visualization of some disorders. This includes rectal, vaginal, and external palpation. The results of blood work, cytology, and histology are commonly used diagnostic aids. Ultrasonography has been used extensively in evaluating the reproductive tract and the abdomen for abnormalities. Hysteroscopy is now a routine technique, and the uses of the laparoscope are well recognized.

PREPARATION FOR SURGERY
Decreasing the volume of ingesta within the intestinal tract generally facilitates elective procedures involving the abdomen, so withholding food for about 24 hours is recommended. However, disruption of a horse’s routine may increase the risk of developing intestinal abnormalities. Many of the disorders involving the uterus are of an emergency nature, requiring well-trained personnel to assist in the management of these conditions.

Anesthesia and Analgesia
Standing surgery of the cranial reproductive tract requires profound sedation, visceral analgesia, and local anesthesia. Xylazine, detomidine, and butorphanol are often used in combination for sedation and analgesia. Epidural anesthesia may help facilitate some procedures. Many of the procedures used for the cranial reproductive tract require general anesthesia. However, there is concern about the effects of inhalation anesthetic agents on the fetus in mares with dystocia and those undergoing a cesarean section (C-section). Therefore, total IV anesthesia (guaifenesin, ketamine, and detomidine) has been recommended for these mares, at least until the foal is delivered.2

For mares that have dystocia, the author has had consistently good results using xylazine, diazepam, and ketamine
Competence with these procedures, particularly ultrasonography and endoscopy, has permitted more rapid and accurate diagnoses, yielding more successful treatment regimens. Despite the benefit gained from these technologies, a complete history and a thorough physical examination are still the foundation of the diagnostic workup. Palpation often provides as much, if not more, information than visualization of some disorders. This includes rectal, vaginal, and external palpation. The results of blood work, cytology, and histology are commonly used diagnostic aids. Ultrasonography has been used extensively in evaluating the reproductive tract and the abdomen for abnormalities. Hysteroscopy is now a routine technique, and the uses of the laparoscope are well recognized.

**PREPARATION FOR SURGERY**

Decreasing the volume of ingesta within the intestinal tract generally facilitates elective procedures involving the abdomen, so withholding food for about 24 hours is recommended. However, disruption of a horse’s routine may increase the risk of developing intestinal abnormalities. Many of the disorders involving the uterus are of an emergency nature, requiring well-trained personnel to assist in the management of these conditions.

**Anesthesia and Analgesia**

Standing surgery of the cranial reproductive tract requires profound sedation, visceral analgesia, and local anesthesia. Xylazine, detomidine, and butorphanol are often used in combination for sedation and analgesia. Epidural anesthesia may help facilitate some procedures. Many of the procedures used for the cranial reproductive tract require general anesthesia. However, there is concern about the effects of inhalation anesthetic agents on the fetus in mares with dystocia and those undergoing a cesarean section (C-section). Therefore, total IV anesthesia (guaifenesin, ketamine, and detomidine) has been recommended for these mares, at least until the foal is delivered.

For mares that have dystocia, the author has had consistently good results using xylazine, diazepam, and ketamine.
for induction, and halothane or isoflurane in oxygen for maintenance of anesthesia. Isoflurane has become the inhalant agent of choice for the horse because of its availability, cost, and anesthetic properties (see Chapter 19). Rapid delivery of the live foal combined with immediate neonatal care provides the best opportunity for the foal’s survival when the mare has dystocia. Anesthesia should be induced rapidly and maintained at a light surgical plane, allowing the procedure to proceed as quickly as possible.

**Laparotomy**

The standing flank approach to the abdomen is primarily used to perform an ovariec-tomy or to correct a uterine torsion. The mare is preferably placed in stocks with moveable sidebars. Routine skin preparation for aseptic surgery and draping are used. A modified grid approach is made through the body wall in the appropriate flank of the horse (see Chapter 33). Complications encountered with this technique include an uncooperative mare, the inability to resolve the disorder (e.g., uterine torsion), and incisional infection.

General anesthesia is required to perform a ventral laparotomy. This procedure can be performed safely, on an elective or an emergency basis, in most surgical facilities by properly trained equine surgeons because of the number of colic surgeries treated at most facilities. The ventral approach to the abdomen, midline or paramedian, provides better access than other approaches and allows faster and safer resolution of most cranial reproductive tract abnormalities. Complications include anesthetic, recovery, and incisional problems.

**Laparoscopy**

The most common use of the laparoscope for the mare’s reproductive tract has been for ovariec-tomy. It has also become useful as a diagnostic tool, and with time, more applications will be developed. Laparoscopy requires special equipment and instruments, an in-depth knowledge of the abdominal and reproductive anatomy, and just as important, extensive surgical training.3

Generally, procedures are performed in the standing horse, with the laparoscope placed through the flank. A ventral approach to the abdomen is occasionally used. Complications generally relate to abdominal organ trauma as a result of placement of the cannula for the telescope and the instruments.

**THE OVARIES**

The most common surgical procedure involving the ovary is resection. This is performed for various conditions and by applying various methods. The procedure used for ovariec-tomy depends on the reason for their resection, the temperament of the mare, the experience of the surgeon, and the cost to the client.

**Neoplastic Conditions**

Granulosa cell tumors (GCTs) are the most common ovarian neoplasm.67 Affected mares may show anestrus, intermittent or continuous estrus, nymphomania, or stallion-like behavior. Generally, the ovary is enlarged, sometimes quite massively, and the contralateral ovary is usually small and inactive. The ultrasonographic appearance is usually that of a multiple cystic structure, although this can vary. Testosterone levels are generally elevated. Inhibin levels are more consistently elevated but not always. Repeated palpation of the ovary may be useful to help rule out other causes of the enlargement.

A GCT most commonly develops unilaterally, but it can occur bilaterally; it is usually benign, but it may exhibit metastases.4,5,7,8 The tumor can develop in mares of all ages, and a juvenile form has been reported in the neonate.4,9 Unusual abnormalities associated with GTCs have been noted, including hemoperitoneum, adhesions to adjacent organs, and small colon strangulation obstruction.5-13 Ovariectomy is usually needed to resolve these conditions.

Other neoplastic conditions of the ovary are rare. They include teratoma, cystadenoma, adenocarcinoma, lymphosarcoma, melanoma, dysgerminoma, and ar-rhenoblastoma.5,6,14-20

**Nonneoplastic Conditions**

An enlarged ovary may have nonneoplastic causes.6,21,22 Occasionally, hematomas and cysts become quite large and adversely affect ovarian architecture. Abscessation can cause an enlarged, painful ovary. Ovariectomy is usually needed to resolve these conditions.

Abnormal behavior is occasionally encountered in show mares during estrus. If hormone therapy is unsuccessful, bilateral ovariec-tomy can be used to correct this behavior.

**Ovariectomy**

**Colpotomy**

Ovariectomy via a colpotomy has been used primarily for bilateral ovariec-tomy, either to effect an improvement in a mare’s behavior or for research applications. The procedure has been used for years and has changed little, except for improvements such as surgical gloves and anesthetics and analgesics.6,23-25

The mare is sedated and placed in stocks, and the tail is wrapped. Epidural anesthesia is generally recommended. The rectum is evacuated, and the bladder is emptied if it is distended. The tail is tied upward and the perineal region is prepared for surgery. A pointed bistoury or guarded scalpel is used to make a small incision through the cranial vaginal wall, 4 to 5 cm caudal to the cervix. The incision is made at the 2- or 4-o’clock position if the surgeon is right handed, or at the 8- or 10-o’clock position if the surgeon is left handed. These sites avoid inadvertent penetration of the bladder, rectum, and uterine branch of the urogenital artery laterally. The peritoneum is penetrated with a thrust from closed blunt-pointed scissors. This small incision is enlarged digitally until the entire hand can pass into the peritoneal cavity (Fig. 68-1). Lidocaine-soaked gauze sponges, tethered with a long strand of umbilical tape, are held around the ovarian pedicle for 1 minute. The chain loop of the écraseur is placed around an ovary, with care taken to exclude other tissues and slowly (over 3 to 4 minutes) tightened until the ovary falls into the surgeon’s hand (see Fig. 68-1, B). The
ovary is removed from the abdomen and the procedure is repeated on the other ovary.

The vaginal incision is allowed to heal as an open wound and the mare is kept standing for 2 to 3 days to prevent the rare case of eventration. Loose apposition of the wound edges with large absorbable sutures may lessen the anxiety level of the surgeon postoperatively. Broad-spectrum antibiotics and anti-inflammatory drugs are administered for 5 days postoperatively, and the mare is walked daily for 2 weeks before resuming previous activities.

Possible complications include excessive (possibly fatal) bleeding from the ovarian pedicle and eventration through the vaginal surgery site.

**Laparotomy**

Ovariectomy via a laparotomy allows the ovary to be exteriorized under visual control, which facilitates direct hemostasis. A flank approach can be used in the standing mare if the ovary is less than 10 cm in diameter and there is concern about general anesthesia. A flank approach may also be used with the mare under general anesthesia. A grid approach through the abdominal muscles is used to access the abdomen. Occasionally, a seroma forms postoperatively at the surgery site.

As mentioned, a ventral approach to the abdomen can be via a midline, paramedian, or diagonal paramedian incision. The ventral midline incision is best for very large ovarian tumors with an ovarian pedicle of adequate length. The diagonal paramedian laparotomy approach is, however, the most useful. The incision is positioned directly over the ovary, so less tension is applied to the ovarian pedicle during vessel ligation than with other procedures.

The mare is anesthetized and placed in dorsal recumbency, and the surgery site is prepared for aseptic surgery. A 12- to 15-cm incision is made starting about 5 cm cranial to the mammary gland and nearly bisecting the angle formed by the ventral midline and the inguinal depression. An attempt is made to avoid any large subcutaneous vessels. The incision is continued through the external rectus sheath. The rectus abdominis muscle fibers are bluntly separated, and the internal rectus sheath is opened carefully with scissors. A hand is introduced into the peritoneal cavity, and the ovary is found and carefully exteriorized. Stay sutures are placed in the ovary. Distended follicles may need to be aspirated to allow passage of the enlarged ovary through the incision. Smaller ovaries can be pushed up to the incision per rectum by an assistant. Ligatures are placed around the cranial and caudal margins of the ovarian pedicle and used as stay sutures. A 90-mm thoracoabdominal stapling device (TA 90; United States Surgical Corp, Norwalk, Conn) is placed across the ovarian pedicle and discharged. The ovarian pedicle is transected between the rows of staples and the ovary, which is removed from the abdomen (Fig. 68-2). After removal of the stapling device, tension is relieved on the end of the ovarian pedicle while still holding the stay sutures, and the transection site is checked for bleeding. Extra ligatures are used as needed. In very large GCTs that are difficult to exteriorize out of the abdomen, some surgeons prefer to separate the tumor from the pedicle in the abdomen with the help of an écraseur. Care must be taken to leave approximately a 2-cm stump of the pedicle with the tumor. Separation through the écraseur should be accomplished over a 3- to 4-minute period. After the tumor is removed from the abdomen, the large vessels in the pedicle are ligated or closed with staples to prevent postoperative hemorrhage. The ovarian pedicle is placed back into the abdomen and the abdomen is closed. The rectus abdominis muscle fibers are reapposed with no. 2 absorbable suture in an interrupted cruciate pattern. The rectus abdominis muscle fascia is closed with no. 2 absorbable suture in a continuous pattern, the subcutaneous tissue with no. 1 absorbable suture in a continuous pattern, and the skin with no. 0 absorbable suture in a continuous pattern. An
experienced surgeon is able to perform this procedure bilaterally, if needed, in a relatively short time.29

Postoperative instructions include 1 week of hand-walking, followed by 2 weeks of small-paddock turn-out and subsequent routine care. The rare postoperative complications include postoperative abdominal pain and incisional infection.

Laparoscopy

Ovariectomy using the laparoscope is the treatment of choice in some hospitals.3,29–38 The laparoscope allows visualization and manipulation of the ovary in situ. Various methods of hemostasis can be applied with minimal tension on the ovarian pedicle.38 However, a distinct advantage of using the laparoscope is to perform the procedure in the standing mare.

The mare is sedated, usually with detomidine and butorphanol, and placed in stocks, and the surgery sites are prepared for aseptic surgery. Local anesthesia is used at the laparoscopic portal sites in the flank. For a bilateral ovariectomy, three small incisions are made in the left flank, which is safer for the initial approach because it minimizes the risk of cecal trauma. The dorsal incision is initially used to pass a cannula with a blunt trocar through the peritoneal lining. The abdomen is subsequently insufflated with CO2. The laparoscope is placed through this cannula, and the other portals are used for instruments. Lidocaine is administered through a laparoscopic injection needle (Karl Storz Veterinary Endoscopy, Goleta, Calif) to desensitize the ovarian pedicle.

Various methods have been used for hemostasis and resection of the ovary, including the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, laparoscopic scissors and stapling instruments, ligatures tied in a modified Roeder knot or Tayside slipping knot, electrocoagulation, and ultrasonic instruments that cut and coagulate. One of the ventral portals is enlarged to remove the ovary. If the ovary is much larger than 10 cm in diameter, a hand-assisted laparoscopic technique can be used in the standing mare. In a recent report, ovaries up to 40 cm in diameter were removed using this technique.35 The procedure is repeated on the contralateral side if a bilateral ovariectomy is to be performed. The incisions are closed after deflating the abdomen and removing the cannulas.

Postoperative care includes antibiotics and anti-inflammatories for 2 to 3 days, and 2 weeks of hand-walking before returning to routine care. As after a laparotomy, complications are uncommon but include postoperative abdominal discomfort and incisional infection.

THE UTERUS

Uterine Cysts

Uterine or endometrial cysts are most commonly found in older mares and are usually diagnosed by ultrasonography. If many are present, they may have an adverse affect on fertility. If the cysts are suspected to be the cause of infertility, they should be removed. Methods of cyst removal have included mechanical curettage, cyst rupture with endometrial biopsy forceps, uterine lavage with a hypertonic saline or magnesium sulfate solution, electrocoagulation of the cyst, and laser ablation.39,40 In the author’s opinion, laser ablation has been the most successful and most accepted technique.

The mare is sedated and placed in stocks, and the perineal region is prepared for hysteroscopy. A 1-m videoendoscope that has been cold-sterilized and rinsed with sterile water is passed through the cervix into the uterus. The uterus is distended with air to allow visualization of the body and both horns. The uterine cysts are first opened and drained. A diode laser, set at 14 W, is used to ablate the cysts. Lasing is continued until the remaining cystic tissue is shriveled and burned. Smoke and fluid often need to be evacuated from the uterus a few times during the procedure. Immediately after the procedure, the uterus is lavaged or infused with antibiotics. An ultrasonographic examination of the uterus should be performed prior to breeding. A recent report of the use of the Nd:YAG laser to ablate endometrial cysts in 55 barren mares demonstrated improved fertility.40

Uterine Neoplasia and Pyometra

Uterine neoplasia and chronic pyometra are rare conditions that are treated by ovariohysterectomy.25,39,41–49 The most commonly encountered uterine tumors are leiomyoma and leiomyosarcoma, and botryoid rhabdomyosarcoma has also been reported. Chronic pyometra is generally the result of an obstruction of complete drainage. Drainage of the uterine contents prior to surgery is advisable.
Partial ovariohysterectomy has been used to remove a focal uterine tumor and ovarian masses with adhesions to the uterine horn.22,47-49 The approaches have included a caudal ventral midline and paramedian laparotomy and a standing flank laparoscopy. Live foals have been produced by mares after partial ovariohysterectomy.42,46,49

Total ovariohysterectomy is best approached through a caudal ventral midline incision. The ovarian pedicles are ligated, and dissection continues through the broad ligament, ligating large vessels in the process. The body of the uterus is transected as far caudal as possible, with care taken to avoid contamination of the peritoneal cavity. The uterine stump is closed with a double-inverting suture pattern. The abdomen is closed in routine fashion.

Uterine Torsion
Mares with uterine torsion are initially examined for signs of colic. Affected mares usually exhibit mild to moderate, intermittent abdominal pain. The diagnosis is usually made by rectal examination. In most cases, a taut broad ligament is palpable, coursing dorsal to the caudal aspect of the uterus in the direction of the torsion. An ultrasonographic examination may provide useful information about fetal viability, status of the uterus, and other abdominal abnormalities.

Uterine torsion can affect mares of all ages, usually during the last 2 months of gestation, although this varies.30-38 The direction of the torsion may be clockwise or counterclockwise, and the majority are turned 180 degrees. Uterine torsion is usually diagnosed in its acute stage, although chronic uterine torsion has been reported.53 Nonsurgical management usually requires general anesthesia and rolling of the mare. The few mares that are at term may be successfully corrected by passing a hand into the uterus, grasping the fetus, and gradually rocking it, together with the uterus, in larger and larger arcs until it untwists.50,54

The procedure for rolling involves anesthetizing the mare and rolling her 360 degrees in the direction of the torsion. A long wooden plank, firmly placed across the mare’s flank, is helpful in keeping the gravid uterus in the same position while the mare is rolled around it. This method of management has been quite successful.23,24 However, uterine rupture in a mare at term has been reported.53

Surgical management of uterine torsion is frequently used. The standing flank approach has been more popular than the ventral midline approach.* The mare is sedated and placed in stocks. Local anesthesia is administered and routine surgical preparations are made. The flank incision is made on the side toward which the uterus is twisted. A modified grid approach is made through the body wall. An arm is introduced and a hand is placed under the gravid uterine horn. The uterus is gradually rocked back and forth, eventually allowing the uterus to flip back into its normal position. The status of the fetus and of the uterus should be evaluated. Closure is routine.

A ventral midline approach should be used if uterine rupture, tearing, or devitalization is suspected, if the foal is known to be dead and the mare is preterm, and if attempts at standing correction are unsuccessful.55 If the mare is in a surgical facility where many abdominal surgeries are performed, the ventral midline approach should be considered instead of the flank approach, since it is more versatile.

The most frequently referenced review of uterine torsions (1981) revealed 19 of 26 (73%) of the mares survived, and of 20 foals determined viable at surgery, 12 (70%) were foaled normally.39 The success rates for mare and foal survival are likely to have improved since that review.

Uterine Prolapse
Uterine prolapse in the mare rarely occurs.25,39,58 It tends to occur more frequently after dystocia and when fetal membranes are retained. Tension placed on the placenta and the use of excessive oxytocin have also been implicated.39 Although rare, the condition may be complicated by bladder prolapse, uterine tear, intestinal herniation, or uterine vessel rupture.

In the initial stages, this is quite painful for the mare. Sedation is indicated. Tocolytic agents, if available, may help decrease straining and discomfort. Prompt treatment is important. The uterus should be cleaned with saline and any placenta not directly attached to the uterus resected. Keeping the uterus elevated and protected in a plastic bag until definitive treatment is started reduces swelling, contamination, trauma, and straining.

Occasionally, the uterus can be replaced in the standing mare if it is heavily sedated. Copious amounts of lubricant are used, and the uterus is gradually pushed back into its normal position. The use of fingertips should be avoided. The author does not use epidural anesthesia, since it does not tend to eliminate all straining, and its use is contraindicated if general anesthesia is needed. If standing uterine replacement is unsuccessful, the mare is anesthetized and her hind limbs hoisted. Then, the uterus can be replaced relatively easily into its normal position. Care is taken to ensure that the uterine horns are fully extended. The vulva is sutured, except for a small ventral opening, and the mare is recovered. The mare is treated with antibiotics, anti-inflammatories, and IV fluids if needed. Uterine lavages commence the next day. Although oxytocin is recommended by some,58 the author avoids its use for 2 to 3 days.

Uterine Rupture
Uterine rupture or tear usually occurs during a dystocia or normal foaling, but rarely it can also occur with uterine torsion or hydramnios.30,60 Most tears are not appreciated for 24 to 72 hours postpartum.25,39 Uterine or vaginal tears are infrequently associated with evisceration of bowel during foaling. In this situation, the bowel should be cleansed and replaced in the abdomen prior to delivering the foal. The tear should then be identified and a plan formulated for repair. Very rarely, a fetus may gain access to the abdomen through a uterine tear, necessitating abdominal surgery to deliver the foal and repair the uterus.

Tears in the uterine body are sometimes found relatively early postpartum by palpation of the cervix and caudal vagina during uterine lavage. However, palpation of a tear at

*References 25, 39, 50, 51, 54, 55.
that site can be difficult postpartum because of the swelling and folding of the uterine lining.

Most uterine ruptures are diagnosed 1 to 3 days postpartum, when the mare presents with depression, fever, and mild abdominal discomfort. In the presence of an elevated peritoneal fluid white blood cell count and protein level, uterine rupture becomes the most likely diagnosis.

Uterine rupture can be fatal, but with prompt diagnosis and treatment the prognosis for survival is good. In a study of postpartum mare death over a 2-year period, 6 of 98 mares died from a perforated uterus.61 Earlier reports of mares with uterine rupture yielded survival rates of 39% and 60%.62,63 A more recent study of 33 mares revealed an 80% survival rate.64 Although medical management may occasionally be successful, surgical repair yields a more consistently successful result.

Information obtained from the more recent study just mentioned revealed that 73% of the perforations occurred in the uterine horn and 27% in the uterine body64 (Fig. 68-3). Interestingly, only 10 of the 33 mares had encountered dystocia. All of the uterine tears in this study were repaired surgically. All of the uterine horn and some of the uterine body tears were accessed through a caudal ventral midline celiotomy. These defects were closed using a simple-continuous pattern and oversewn with a continuous inverting pattern, both using no. 1 multifilament absorbable suture. The abdomens were lavaged during surgery and for 2 to 3 days postoperatively. Uterine lavage started 1 day postoperatively and continued for 3 to 4 days. Some perforations in the caudal body of the uterus were repaired in the standing mare per vagina. Closure consisted of a single layer of simple-interrupted or continuous sutures.

Uterine Artery Hemorrhage

Hemorrhage from the uterine arteries (i.e., the uterine branch of the vaginal artery), the uterine artery, and the uterine branch of the ovarian artery is the most common cause of death of the postpartum mare. A study of 98 mares that died postpartum revealed that 40 died from a ruptured uterine artery.65 It is uncommon for these arteries to rupture at times other than in the first several days postpartum.

The condition is usually seen in older mares. Affected mares are often initially in quite an amount of pain, especially if the blood is contained within the broad ligament. The rectal examination in these mares generally reveals a fluctuant mass in the broad ligament. If the broad ligament ruptures and the blood gains access to the abdominal cavity, the mare may not exhibit as much pain. On rectal examination, the broad ligament has a more edematous feel. These mares generally have very pale mucous membranes, a weak pulse, and an elevated heart rate, and they are anxious and often sweating.

Treatment varies depending on the clinician, but it essentially follows the approach taken for hemorrhagic shock (see Chapters 1 and 4).66 Attempts to ligate the ruptured artery have met with limited success.

Cesarean Section

Elective C-Section

Candidates for an elective C-section include mares that have a compromised birth canal as a result of a previous pelvic fracture or a soft tissue injury within the reproductive tract, and mares that have previously had a difficult dystocia or a severe uterine artery hemorrhage. This surgery has also been used to produce gnotobiotic foals for research purposes.65 The surgery must be well timed to yield a viable foal and have minimal adverse effects on the mare, so it is important to perform it as close as possible to the natural foaling time. The mare should be hospitalized 7 to 10 days prior to her due date. Her physical status is checked frequently to determine udder development, softening of her perineal tissues, and behavior. Concentrations of electrolytes in the mammary secretions are very helpful for timing the surgery.66 Decreasing sodium and increasing potassium and calcium levels are good indicators of impending parturition. The surgery, when performed, should proceed rapidly, with knowledgeable staff waiting to resuscitate the anesthetized foal on delivery. The fetal survival rate following elective C-section is about 90%.67,69

Emergency C-Section

The most common reason to perform a C-section in the mare is to resolve a dystocia.61-66,69-72 This is truly an emergency situation and once the decision is made, the C-section should proceed rapidly. The team of people involved should be well organized and prepared for this situation. Other circumstances potentially needing an emergency C-section include a near-term mare undergoing colic surgery or correction for uterine torsion. Ideally, if the mare has a good prognosis to survive, the fetus should remain in the mare until normal parturition. A C-section should be performed if the mare has a guarded prognosis. A recent study showed only 3 of 8 (38%) term foals delivered during colic surgery survived to discharge.69 It would be rare to encounter significant incisional complications during parturition after a recent abdominal surgery.

Figure 68-3. Typical appearance of a uterine tear at the tip of the uterine horn.
Surgical Technique

As the obstetrical manipulations for controlled vaginal delivery are being performed, the ventral midline of the mare is being prepared for a possible C-section. Once the decision is made, the surgery room is set up and the mare is positioned on the surgery table and readied for surgery. The time from the decision to perform a C-section to the delivery of the foal should be no more than 20 minutes. This is the same for elective and emergency C-section. If the foal is known to be dead, this time is not as critical.

The two most commonly used approaches for C-section in the mare are the modified low flank (Marcenc) and the ventral midline. The modified low flank approach, which positions the horse in lateral recumbency, is used to be popular in Europe. The most rapid approach to the abdomen, and the approach most commonly used in North America, is the caudal ventral midline approach.

The mare is positioned in dorsal lateral recumbency with the ventral midline tilted toward the surgeon. A 35- to 40-cm incision is made into the abdomen beginning 10 cm caudal to the umbilicus and extending craniod. The gravid uterine horn, which usually contains the hind limbs of the fetus, is located and exteriorized. One stay suture is placed in a cruciate pattern near the tip of the uterine horn, close to the position of the fetal feet, and another toward the body of the uterus, close to the position of the fetal hocks. An assistant surgeon handles the stay sutures during the procedure to minimize contamination of the abdomen with uterine fluids and to help facilitate closure. An extra impermeable drape is placed over the other drapes on the surgeon’s side of the abdomen.

An incision is made through the uterine wall and chorioallantois from the level of the fetal hocks to the feet, creating a straight incision between the stay sutures (Fig. 68-4). During extraction of the fetus, it is not uncommon to have the uterine wall tear slightly at the end of the uterotomy incision. The amniotic membrane, which has collapsed around the foal, is elevated and incised. The surgeon grasps the hind limbs and lifts the fetus up and out of the uterus. The hind limbs are handed to a third assistant, and the surgeon pulls the body up and out of the uterus. In this manner, the fetus is pulled from the mare rapidly. The umbilical cord is clamped and transected and the neonate is quickly transferred to a table set up just outside the surgery room for resuscitation and evaluation. The chorioallantois is separated from the endometrium for 3 to 4 cm along the incised edge of the uterine wall. If the placenta separates easily from the uterus, it may be entirely removed at that time. However, it is usually still well attached.

Infrequently, the hind limbs are not present in a uterine horn, making it extremely difficult to exteriorize any part of the uterus. The uterine incision is then made at the base of a horn and body of the uterus with the uterus in the abdomen. This causes significant concern about the amount of contamination occurring during surgery. (After closure of the uterus, the abdomen will be lavaged with copious amounts of saline.)

The incised edge of the uterine wall bleeds profusely. A continuous suture line is placed along this edge to provide some hemostasis. Large vessels are individually ligated. The need for the hemostatic suture line has recently been questioned. This author feels that it lessens the risk of bleeding enough to warrant the 10 minutes needed for its placement. The assistant elevates and tenses the stay sutures to facilitate closure of the uterus, which is performed in 2 layers with no. 1 or 2 absorbable suture material. A continuous Connell pattern is used for the first layer, and a continuous Lembert for the second layer. After uterine closure, the uterus is lavaged and 40 units of oxytocin is administered IV. This quickly stimulates contraction of the uterus and aids expulsion of the placenta. The stay sutures are removed and the uterus is replaced into its normal position in the abdomen.

The extra impermeable drape is removed, the drape surface around the incision is lavaged, and the surgeon’s gown and gloves are changed if needed. The abdomen is lavaged with 10 to 15 L of warm saline, which is removed by suction. An abdominal drain for subsequent lavage may be placed if deemed necessary. A crystalline penicillin solution is instilled into the abdomen, which is closed in routine fashion for a ventral midline celiotomy.

Terminal C-Section

Significant concern for a foal in a mare with a terminal illness may require a C-section. Examples include mares recumbent as a result of neurologic abnormalities, severe laminitis, or other potentially fatal or debilitating conditions. If euthanasia is planned for the mare after the surgery, sterility is not a high priority but speed of delivery is. Most of these surgeries can be performed quickly through a low flank approach after induction of anesthesia.

Aftercare

Postoperative care for a C-section mare is very similar to that for any mare after abdominal surgery, with special attention paid to the reproductive tract. Some mares pass their placenta in the recovery stall. If the placenta has not passed, oxytocin is again administered 2 to 3 hours postpartum. The initial dose is 40 U in 1 L of lactated Ringer’s solution given IV over 30 to 60 minutes. Since this often causes abdominal pain, the rate of administration is dictated by the response of the mare. In refractory cases, 80 U is used every 4 to 6 hours. Usually, the placenta passes within 8 hours postpartum. Manual rupture of the chorioallantoic

Figure 68-4. Uterotomy with stay sutures in place. The amnion is partially incised near the point of the hock.
membrane and exteriorization of the amniotic membrane per vaginam may be needed to initiate placental expulsion after an elective C-section. Uterine lavage is started soon after the placenta is passed, or simultaneously if it is retained. The uterus is generally lavaged once daily for 3 to 4 days.

Systemic antibiotics and flunixin meglumine are administered for 3 to 5 days after the delivery, depending on the degree of contamination and tissue trauma encountered. Intravenous fluids are administered as needed to maintain adequate hydration and vascular volume and to correct electrolyte imbalances. Abdominal surgery, even without manipulation of the intestines, combined with possible bruising of the small colon or cecum from the dystocia, can result in transient postoperative ileus. Swollen and painful pelvic tissues may lead to retention of feces. The postpartum diet should reflect concern for these potential problems. Water is offered freely. The mare is walked and allowed to graze on green grass the first postoperative day. A bran mash with mineral oil may be beneficial. Discharge instructions include hand walking 2 to 3 times each day, with or without small-paddock turn-out for 3 to 4 weeks.

DYSTOCIA

Dystocia in the mare is one of the few true emergencies an equine practitioner may encounter. Prompt action increases the probability of survival of the foal and decreases the degree of reproductive trauma to the mare. There are four procedures to resolve dystocia: assisted vaginal delivery, in which the mare is awake and is assisted in the vaginal delivery of an intact foal; controlled vaginal delivery (CVD), in which the mare is anesthetized and the clinician is in complete control of the delivery of an intact foal vaginally; fetotomy, in which the dead fetus is divided into more than one part for removal from the uterus per vaginam in an awake or an anesthetized mare; and C-section, in which the fetus is removed through an incision in the uterus.

The goal of dystocia resolution is to deliver a live foal in a manner resulting in a reproductively sound mare. This is usually accomplished at the farm. However, referral hospitals need to be prepared for difficult cases, and the clinician must be able to perform whatever procedure is necessary to resolve any dystocia. Currently, emergency clinicians, who are usually trained as surgeons or internists, tend to perform C-sections at these hospitals. Thus, these clinicians should also be familiar with CVD and fetotomy techniques. No single procedure is right for every situation.

Once the mare is in the hospital, dystocia requires prompt action. The mare is anesthetized shortly after arrival to attempt CVD. The hind limbs are hoisted upward until the pelvis is about 3 feet above the ground (Fig. 68-5). Decreased straining, gravity, and lubrication usually enable resolution of the dystocia. If the foal cannot be delivered within 15 minutes, a C-section or fetotomy should be considered. C-section techniques were described earlier. Fetotomy techniques are described elsewhere. Results of dystocia resolved in a referral hospital in an area with a high concentration of broodmares were recently examined. Of 247 cases of dystocia, 71% were resolved by CVD, 25% by C-section, and 4% by fetotomy. A live foal was delivered in 42% of cases, and 30% were discharged from the hospital, with 91% of the mares surviving to discharge.

The elapsed time from chorioallantoic membrane rupture to delivery for foals alive at discharge (mean of 72 minutes) was significantly less than for foals not surviving (mean of 85 minutes). The effect on fertility after dystocia was examined in Thoroughbreds in this study. It was shown to be decreased, although still respectable: the pre-dystocia live foaling rate was 84%, whereas the rate after dystocia was 67%.

PATIENT EVALUATION

History
A complete patient history should be obtained as part of any evaluation of a horse with suspected urinary tract disease. Contrary to popular opinion, horses with clinically significant disease of the kidneys or proximal urinary tract typically do not exhibit back pain as a principal clinical sign.1 Veterinarians should be alert for signs of low-grade abdominal pain, weight loss, stranguria, dysuria, hematuria, oliguria, or incontinence.1-3 Of all the primary signs reported by owners of horses with suspected urinary tract disease, abdominal discomfort accompanied by oliguria, anuria, or hemorrhage from the urethra is the most urgent and demands prompt investigation.

Physical Examination
All horses with urologic signs should undergo a complete physical examination. Horses with suspected urinary tract disease should be evaluated for general health status and fitness not only for the diagnosis of the urologic pathology, but also before surgical intervention. Systemic consequences of the urinary tract condition as well as the presence of concurrent systemic disease may have profound effects on the anesthetic course and postoperative care. Patients that are toxemic or suffering from severe electrolyte or acid–base derangements are particularly susceptible to anesthetic crises.

The perineum, tail, and medial surface of the hindlimbs should be inspected for the presence of dried urine, urine scald dermatitis, or blood. If possible, micturition should be observed to establish the presence of abnormal urine flow, incontinence, hematuria, or dysuria. Stranguria is usually accompanied by tail switching or flagging during urination. The volume and quality of the urine should be determined. Finally, all external portions of the urogenital tract should be palpated.

Rectal Examination
A rectal examination is indicated to evaluate the pelvic urethra, bladder, and left kidney. Size, consistency, and position of organs, as well as pain on manipulation, should be noted during palpation. The bladder can be palpated dorsal and slightly cranial to the pubic bone. When the bladder is greatly distended, the cranial edge is usually far forward and off to one side of the abdominal midline. Palpation of the bladder is of greatest value when it is relatively empty. Special attention should be given to evidence of thickening or swellings, as well as intraluminal concretions or calculi. Usually, the ureters and right kidney are not palpable4 unless significant pathology alters their size or position within the abdomen. Distal ureteral calculi are palpable in the trigone region. Ureteral calculi cause dilation and distention proximal to the obstruction. Right renal hydronephrosis or neoplasia can result in renal enlargement or caudal displacement sufficient to permit palpation per rectum. The left kidney is generally palpated medial to the spleen and ventral to the lumbar spine.4 Typically, it is a smooth-surfaced, bean-shaped structure that can be moved to the left body wall to permit percutaneous biopsy5,6 (see Chapter 70).

Clinical Pathology
Preoperative laboratory examinations of surgical patients should include a complete blood count; determination of serum urea nitrogen, creatinine, and electrolyte values; and urinalysis. When reduced renal function is suspected, urine glutamyl transpeptidase levels and sodium sulfanilate clearance may be determined.3,7-10 Fractional excretion of electrolytes is also important in determining renal function. Evaluation of blood pH and base excess may be helpful, particularly in surgical cases involving uroperitoneum. Preoperative identification and correction of metabolic acidemia and electrolyte abnormalities are often important to patient survival; foals suffering from cystorrhexis (ruptured bladder) and uroperitoneum frequently develop severe metabolic acidemia and hyperkalemia,11 which may result in anesthetic or postanesthetic death of cardiac origin.12

Imaging Techniques

Radiography and Nuclear Scintigraphy
A variety of modalities are available for imaging the distal urinary tract. Radiography is effective for evaluation of the proximal urinary tract of foals and young horses. In adult horses, large patient size and technical problems—associated with radiation scatter and definitive radiographic interpretation—generally preclude effective imaging of proximal urinary tract diseases. Positive-, negative-, or double-contrast cystography enhances the value of a radiographic
examination of pediatric or young adult patients suspected of suffering from distal urinary obstruction or hemorrhage. When a diagnosis of ectopic ureter is suspected, intravenous pyelography is potentially useful for identification of the abnormal course and insertion of the involved ureters. Intravenous contrast agents should be used with caution because of reports of acute renal failure in humans. Presumably, many of these problems are the result of organ ischemia subsequent to vascular occlusion of the arteries by injection catheters, a situation not likely to occur during the performance of an excretory urogram. Kidneys affected in this way demonstrate intense and prolonged staining characteristics.

Recently, nuclear scintigraphy has been used to determine renal function in horses. The use of technetium-99m–labeled diethylenetriamine penta-acetic acid or iodine-131-orthoiridohippuric acid has permitted measurement of glomerular filtration rate, renal plasma, and blood flow in horses. Nuclear scintigraphy can be used to confirm the lack of blood flow or loss of function to the pathologic kidney while simultaneously documenting the health of the contralateral kidney prior to nephrectomy (Fig. 69-1).

**Ultrasonography**

Ultrasonographic examination of the equine urinary tract has value in the diagnosis of a variety of clinical conditions. This imaging modality permits evaluation of the kidneys for changes in size, shape, and consistency or echogenicity. It aids in the diagnosis of renal calculi, ureteral obstruction, hydronephrosis, renal cysts, abscesses, tumors, and developmental anomalies. Typically, a 3-MHz transducer with a 15- to 20-cm field of view is required for transmural ultrasonography of adult horse kidneys. The right kidney can be imaged at the 15th, 16th, or 17th intercostal space below the level of the transverse processes. The left kidney is imaged through the 17th intercostal space or immediately caudal to the 18th rib, where it lies deep to the spleen (Fig. 69-2). Transrectal scanning techniques can be used with 5- to 10-MHz transducers for detailed evaluation of the renal pelvis or ureters.

Ultrasonography is especially useful for guided needle biopsy of the kidney, where the needle can be directed toward areas of altered renal echogenicity or tissue of questionable integrity. This ability to identify and avoid renal vasculature reduces the likelihood of perirenal hematoma formation. Whenever unilateral renal or ureteral disease has been identified and resection of the affected kidney alone or together with the proximal ureter is contemplated, the contralateral kidney should be ultrasonically imaged and biopsied. Additionally, analysis of urine from the individual kidneys facilitated by catheterization of ureters may also be required to determine that the contralateral kidney is normal and free of degenerative processes.

Evaluation of the foal bladder and umbilical remnants with ultrasonographic examination has generally replaced standard and contrast radiography as the imaging modality of choice. Normal limits for size of umbilical structures and fetal remnants have been established (see Chapter 71). Pathologic increases in the cross-sectional area and echogenic appearance of these fetal structures is commonly seen with bacterial infections. In addition, rents through the bladder can be identified by urinary catheter placement and ultrasonographic "bubblegram" (Fig. 69-3).

**Endoscopy**

The distal urinary tracts of male and female horses of nearly all ages can be examined with fiberoptic or videoendoscopic instruments. The short, wide urethra of the female permits indirect inspection with either rigid scopes or flexible
The use of catheter stents is controversial, and chronic placement of catheters or silicone or polyethylene cannulae. However, the placement can be facilitated by using sterile flexible rubber urethral catheters and intra-operative stenting of the urethra or ureters for electrosurgery, the use of fine-needle electrodes and scalpels is appropriate. Anastomotic procedures and intra-operative stenting of the urethra or ureters can be facilitated by using sterile flexible rubber urethral catheters or silicone or polyethylene cannulae. However, the use of catheter stents is controversial, and chronic placement appears to promote stricture formation of anastomosed ureters. If stent catheters are used, they should probably be removed as soon as possible, preferably within 5 to 7 days after surgery. A magnifying loupe or an operating microscope and adequate lighting are useful for repair of ureteral defects.

**Suture Material**

Suture materials in a variety of sizes and strengths are required when performing urinary tract surgery. Tissues, such as the neonatal bladder, may be weak or friable, whereas bladders containing cystic calculi may be chronically thickened. Sutures should be selected with some appreciation of specific tissue strength and regenerative capacity. The bladder is considered to be one of the weakest tissues in the human body. Nevertheless, bladders and ureters have a high regenerative capacity and heal readily. For these reasons, sustained strength typically associated with the use of nonabsorbable suture materials is not required.

In fact, nonabsorbable sutures should not be used for closure of any structure of the urinary tract. Nonabsorbable sutures serve as a nidus for formation of urinary concretions. As a technical point of urinary tract surgery, no suture material of any type should be placed in such a fashion that it penetrates the urinary epithelium and is exposed to urine. When synthetic absorbable sutures are exposed to alkaline urine (commonly found in herbivores or carnivores with urinary tract infections), suture hydrolysis may be accelerated.

A comparative study of bursting strength of rat bladders sutured with 5-0 polyglycolic acid, 6-0 surgical gut, and 7-0 chromic gut suggested that infusion pressures of up to 550 mm Hg are required to induce failure. Voiding pressures of most mammals are considerably lower. The voiding pressures of adult ponies and mares have been determined to be approximately 90 mm Hg. The use of 2-0 or 1-0 suture material is adequate to maintain primary closure of incisions in the pressurized portions of the equine distal urinary tract.

Absorbable staples may provide an alternative method of closure of hollow organs, including the bladder. Bladders closed with absorbable staples must be oversewn with a continuous inverting pattern to reduce the formation of adhesions. The use of nonabsorbable staples in the bladder is not recommended based on the formation of a urolith in one case report.

**Laparoscopy**

The use of the laparoscope as a minimally invasive procedure in equine surgery has greatly expanded over recent years. The horse is well suited to laparoscopic techniques because of its size and the anatomic limitations in dealing with several urologic surgical procedures. Standard laparoscopic equipment and instrumentation (described in Chapter 14) can be used for several surgical procedures of the urinary tract, including, but not limited to, exploratory laparotomy, nephrectomy, renal biopsy, umbilical remnant resection, cystic calculi removal, and urinary bladder repair. Hand-assisted techniques combine the benefits of laparoscopic and open surgical approaches. Advantages over laparoscopic techniques alone are seen in the ability to perform manual dissection and retraction, as well as an increase in the safety factor when controlling hemorrhage. As
experience is gained and applications are contemplated, additional surgical techniques utilizing the laparoscope for urological disorders are likely to be developed.

**Pharmacologic Considerations**

The kidney is a major excretory pathway for many drugs that are administered systemically. As a consequence of its normal filtration and concentrating activities, the kidney is exposed to high levels of drugs and drug metabolites. Therefore, the renal effects of all drugs administered to surgical patients must be considered.36

**ANESTHESIA**

When planning anesthesia for a patient with renal impairment, it is important to minimize the period of surgical anesthesia and any related hypotension. All the fluorinated gas anesthetics are nephrotoxic to some degree; methoxyflurane is the most toxic, followed in decreasing order by enfurane, isoflurane, and halothane.24 A newer inhalant anesthetic, sevoflurane, has cardiopulmonary effects similar to those of isoflurane, and it has the theoretical possibility of creating both hepatic and renal toxicity through the formation of compound A via the interaction between metabolites and CO2 absorbents.37,38 Despite the potential for the formation of toxic metabolites, sevoflurane has been used on over 120 million human patients without one report of renal-induced toxicity.36 Halothane undergoes more hepatic metabolism than other inhalants, but formation of toxic waste products appears to be minimal.39 Halothane is a widely used anesthetic agent for horses.40 Its reduced degree of metabolism renders it relatively less toxic for use in renally impaired horses. Alternatively, isoflurane is useful in critically ill horses and has few renal effects,41 which are limited to an increase in urine flow and an increase in serum glucose.43

The kidney is sensitive to hypoperfusion resulting from hypotension. Anesthesia often produces variable degrees of depression of myocardial contractility, heart rate, and cardiac output. Several commonly used anesthetic agents also produce some degree of peripheral vasodilation, which may result in reflex renal vasoconstriction, and associated renal perfusion.45 Renal damage may be avoided by maintaining renal blood flow and minimizing the duration and magnitude of hypotension associated with general anesthesia. Intraoperative administration of balanced fluids enhances perfusion of the functional kidney by improving cardiac output.

Selective vasopressors such as dobutamine or dopamine increase cardiac output and enhance renal perfusion.44,45 The use of an α-blocker as a premedication reduces the degree of catecholamine-induced vasoconstriction and improves renal perfusion in some anesthetized patients.46

Xylazine is a sedative hypnotic agent commonly administered to horses to facilitate examination or as a preanesthetic medication. Xylazine has a dose-dependent diuretic effect.47 Horses with uncomplicated obstructive disease of the lower urinary tract that are at risk for acute cystorrhesis could be further compromised by the use of sedatives or tranquilizers with diuretic properties.

**ANTIMICROBIAL AGENTS**

Antibiotics are frequently administered to horses undergoing urinary tract surgery. Aminoglycoside antibiotics require special consideration when administered to dehydrated or renally impaired patients. Excretion of aminoglycosides occurs essentially via glomerular filtration without biotransformation.48 As a result, these compounds are retained and concentrated within the renal cortex to levels 20 times that found in plasma.49 Aminoglycosides bind to the brush border of renal tubular cells and produce proximal tubular disease.46,50 Although all aminoglycosides demonstrate some degree of nephrotoxicity, neomycin is the most toxic.51 Kanamycin, gentamicin, tobramycin, amikacin, and streptomycin follow in order of decreasing toxicity.52 Other antimicrobials, notably polymyxin B, selected cephalosporins, and tetracycline degradation products, are variably nephrotoxic and should be avoided unless specifically indicated.48,53

Horses requiring the administration of drugs should be well hydrated and carefully monitored for exacerbation of renal impairment.54 Periodic evaluation of patient hydration, serum urea nitrogen, and creatinine is appropriate. Evaluation of the urine for protein, blood, tubular casts, and γ-glutamyl transpeptidase is also reasonable. Serum drug levels can be monitored for peak and trough concentrations. Trough serum levels of gentamicin greater than 2 µg/mL in humans have been associated with increased nephrotoxicity.54 This has led to the alteration of dosage and time for administration of gentamicin and other aminoglycosides. Currently, the recommendation of 6.6 mg/kg of gentamicin IV every 24 hours is considered to be safe and efficacious in the horse. It has also been documented in clinical cases that gentamicin at 4 mg/kg IV every 24 hours is safe and will result in peak plasma levels of greater than 2 µg/mL, which is required for antimicrobial effectiveness.45

**ANTI-INFLAMMATORY DRUGS**

Nonsteroidal anti-inflammatory drugs (NSAIDs) are routinely administered to equine patients undergoing general anesthesia for major surgery and present a risk to renally impaired patients. For many years, NSAID nephropathy has been recognized as a cause of renal papillary necrosis in rats,56 humans receiving aspirin,57 and horses administered phenylbutazone.58 Nonselective NSAID administration reduces the levels of all prostaglandins, including those responsible for maintenance of renal vasculature and perfusion. Therefore, renally impaired horses requiring NSAID medications should receive reduced dosages, ranging from one-fifth to one-third the normal dosage, in an effort to reduce thromboxane concentration without altering renal prostaglandins.59

CHAPTER 70

Kidneys and Ureters
James D. Lillich
Andrew T. Fischer, Jr.
Richard M. DeBowes

ANATOMY
The kidneys of the horse are located retroperitoneally in the left and right lumbar regions. The left kidney lies deep to the lumbar fascia of the psoas musculature in a paramedian position between the 17th rib and the 3rd lumbar vertebra. Laterally, the left kidney is related to the spleen and the renosplenic ligament; ventrally, to the jejunum and descending colon; and medially, to the adrenal glands and left lobe of the pancreas. The right kidney is located in a right paramedian position, more cranial than the left kidney, and between the 16th rib and the 1st lumbar vertebra. Dorsally, the right kidney is related to the right crus of the diaphragm; medially, to the adrenal gland and pancreas; and ventrally, to the cecum. Only the lateral aspect of the right kidney is covered by peritoneum. The renal arteries, which arise from the aorta, frequently branch before penetrating the renal parenchyma. Accessory branches of the renal arteries that penetrate the cranial or caudal poles of the kidney are found occasionally.

The ureters arise from the renal pelvis of each kidney and course laterally and retroperitoneally from their dorsal paramedian origin to the trigone of the bladder, where they insert in a dorsolateral position cranial to the renal crest. In the mare, the caudal ureters can be found in the attached border of the lateral ligaments of the bladder. The ureters of the adult horse are typically 70 cm long and have a diameter of 0.5 to 1 cm.

DISORDERS REQUIRING SURGERY
Surgery of the proximal urinary tract of the horse is both tedious and difficult. Postmortem findings in 364 horses suggest that the frequency of renal disease is 3.84%. The frequency of renal or ureteral disease treatable by surgical methods is presumably lower. Furthermore, candidates for renal surgery (other than elective biopsy) must have renal pathology confined to one kidney. Horses with unilateral renal pathology treatable with surgery are a select minority. Patients with bilateral renal disease such as polycystic kidneys or chronic renal failure secondary to obstructive disease are generally not candidates for renal surgery. Possible indications for renal surgery include the presence of renal calculi, neoplasia, hydronephrosis, unilateral pyelonephritis, ectopic ureter, and renal dysplasia. Surgical disease of the equine ureter is also uncommon. Reports of ureteral surgery are infrequent, because ureteral disease rarely exists as an isolated entity.

Potential surgical indications include ureteral calculi, ureterorhesis, ectopic ureter, or rare conditions such as ureteropelvic polyps.

Renal and Ureteral Calculi
Urine calculi are formed from hydrated crystals of calcium carbonate. Although uncommon, these calculi can become large and produce extensive damage to the kidney, either by causing an obstructive hydronephrosis or by direct encroachment on the renal parenchyma. Select cases, diagnosed early in the course of the disease, can be treated by nephrotomy or nephrostomy. Chronic cases can involve calculi of exceptional size and require treatment by nephrectomy. It is possible for smaller calculi to move distally and lodge in the distal ureter, resulting in obstructive hydroureter and hydronephrosis.

Clinical signs of obstructive renal or ureteral disease are often nonspecific and subtle. Horses are usually asymptomatic until advanced renal disease is present. Weight loss, anorexia, lethargy, and colic are more commonly associated with upper urinary tract obstructive disease rather than with altered urination and hematuria.

Rectal identification of a nephrolith is difficult and unlikely unless the calculus is large and located within the left kidney. The diagnosis of nephrolithiasis (or ureterolithiasis) is made most commonly from clinical signs supported by ultrasonographic and endoscopic findings. Percutaneous ultrasonographic examination of an affected kidney is characterized by an echogenic interface with acoustic shadowing deep to the urolith. Kidneys may be enlarged or smaller than expected on ultrasonographic examination. Ureteral calculi can be identified with rectal palpation. Endoscopic examination of the trigone of

Figure 70-1. A solitary hyperechoic nephrolith is evident (arrow) on this transcutaneous ultrasonographic study of the right kidney.
affected horses evaluates the ureters for periodic elimination of urine. Hemorrhage or cloudy discharge at the ureteral openings and failure to observe periodic elimination of urine from ureteral openings are suggestive of a proximal obstruction. Select cases of ureteroliths are usually treated surgically, but there is one case report of successful resolution using electrohydraulic lithotripsy.

Renal Neoplasia and Dysplasia
Renal neoplasia, either primary or metastatic, is rare in horses. However, renal adenomas, primary renal cell carcinomas, undifferentiated renal sarcomas, and metastatic hemangiosarcomas have been documented. A metastatic granulosa cell tumor has been observed by one author. These tumors are typically large and not detected until late in the course of the disease. Renal dysplasia has been reported in the horse and may be secondary to obstruction from benign ureteropelvic polyps. Unilateral disease may be successfully treated with ipsilateral nephrectomy and ureterectomy.

Renal neoplasia is usually diagnosed in older horses and associated with weight loss, anorexia, or hematuria. Primary tumors may metastasize via the renal vein to the lungs, via the renal lymphatics to the regional lymph nodes, or by transperitoneal exfoliation to other abdominal organs. Primary neoplasia of the ureters has not been described.

Pyelonephritis
Pyelonephritis is an uncommon disease of horses. Horses with unilateral involvement that is refractory to medical therapy, or with discrete, singular renal abscesses are treated by nephrectomy. Horses with disseminated bilateral septic nephritis are not candidates for nephrectomy.

Ureterorrhexis
Ureterorrhexis is a relatively rare condition in which the ureter develops a mural defect and leaks urine. Presumably, this condition results from a congenital defect, and fillies are predisposed. In small domestic animals, trauma or obstruction is the most common cause. Acquired defects can result from trauma or obstructive disease in horses, as described in one case report. There is also one case report of urine leakage from the renal pelvis secondary to renal calculi.

Diagnosis of uroperitoneum is made from the clinical history, physical examination findings, and abdominopercutaneous needle aspiration of sterile urine, and ultrasonography. The specific site is identified by excretory urography, ultrasonography, or surgical exploration. Although retroperitoneal extravasation of sterile urine is not considered problematic in humans, extravasation of septic urine or the concurrent presence of urine and bacteria in the tissue results in fulminant septic cellulitis.

Ectopic Ureter
Ectopic ureter is an uncommon developmental condition of horses and results from faulty differentiation of the metanephric duct. There is neither sex nor breed predisposition in horses which is not the case in dogs.

Typically, the anomalous ureters insert distal to the trigone, resulting in urinary incontinence. A history of urinary incontinence since birth leads to the diagnosis, which is confirmed by endoscopy, contrast radiography (Fig. 70-2), or surgical exploration. Affected individuals should be evaluated for the concurrent problems of hydronephrosis and hydroureter (Fig. 70-3). Timely diagnosis appears to be important for successful treatment. Older patients are more difficult to operate on because of their larger size and an increased incidence of acquired hydronephrosis or ascend ing urinary tract infection. The surgical approaches for the management of ureteral ectopia include ureteral transplantation and neoureterostomy. Success is obtained in large
horses with proper patient positioning and visceral retraction. Horses with a unilateral ectopic ureter have been managed successfully by ipsilateral nephrectomy.

**SURGICAL PROCEDURES**

**Renal Biopsy**

Biopsy of the kidney is used to complete the diagnostic evaluation of suspected renal disease and to evaluate the contralateral kidney before unilateral nephrectomy. It may provide diagnostic information not afforded by ultrasonographic examination or excretory urography. Surgical techniques for biopsy of the kidney are based on anatomic landmarks or directed ultrasonic guidance. Ultrasonic guidance provides the added benefit of biopsy of selected areas of sonographically abnormal renal tissue while avoiding major vascular structures.

**Simple Percutaneous Technique**

Percutaneous renal biopsy (without the benefit of ultrasonographic guidance) is obtained after sedation of the horse, aseptic preparation, and regional anesthesia of the left flank. The horse is palpated rectally by one operator, who locates and positions the left kidney over a biopsy needle that has been introduced through the left flank by a second operator. Either a Vim Tru-Cut (Travenol Laboratories, Deerfield, Ill) or a Vim-Silverman (Mueller Company, Chicago, Ill) biopsy needle is used. It is considerably less safe to biopsy the right kidney using this technique, because it is located more cranially and difficult to palpate. The operator’s ability to selectively biopsy discrete regions of the kidney and avoid large vascular structures is minimal.

**Ultrasonographically and Laparoscopically Guided Percutaneous Techniques**

Ultrasonographically guided needle biopsy of the kidney is obtained with the horse restrained in stocks and prepared as described earlier. The left kidney is imaged at the 17th intercostal space or immediately caudal to the 18th rib and identified deep to the spleen. The right kidney is imaged at the 15th or 16th intercostal space immediately ventral to the transverse processes of the lumbar vertebrae. A 3-MHz transducer produces images of both the kidney and the biopsy instrument. Imaging of the left kidney is particularly enhanced by the presence of the spleen interposed between the body wall and the renal parenchyma. Typically, renal parenchyma has a homogeneous low-amplitude image surrounding a more echogenic collecting system.

When the kidney has been located and identified by ultrasonographic scanning, a biopsy needle is introduced through the desensitized skin of the flank and into the deeper tissues. Typically, the scanning plane is oriented in a longitudinal direction, and the biopsy needle is identified (Fig. 70-4). Passage of the biopsy needle through the tissues and into the kidney is monitored, and large vascular structures and loops of bowel are avoided. Because the operator is able to visualize and direct the biopsy needle to specific regions of the kidney under ultrasonic guidance, selected areas of the kidney can be biopsied where altered echogenicity is consistent with renal pathology.

If the ultrasonographic examination identifies gross abnormalities to the architecture of the kidneys or the kidneys cannot be accurately identified, laparoscopic exploration should be considered. Standard equipment and approaches to the abdomen have been described in Chapter 14. In general, an ipsilateral approach is used for laparoscopic assisted biopsies. Biopsy forceps are visually introduced into the abdomen through a separate stab incision made 5 to 10 cm ventral or dorsal to the laparoscope. Perirenal fat may inhibit access to the parenchyma. The biopsy site is checked for hemorrhage and the abdomen is deflated and skin incisions are closed routinely.

**Complications**

Complications of renal biopsy include hemorrhage (predominantly) and infection. Biopsies collected without the benefit of ultrasonographic guidance are periodically associated with perirenal hemorrhage and hematoma formation (Fig. 70-5), the severity of which can vary significantly. Patients that suffer a laceration of a larger vessel may develop a perirenal hematoma. No treatment is required unless active hemorrhage fails to stop. Transfusions or procoagulant therapy is rarely necessary. Some patients develop transient hematuria after renal biopsy, but usually this problem resolves spontaneously within 24 to 36 hours after the biopsy procedure. Infection is rare if aseptic principles are strictly followed. The use of antibiotics after renal biopsy should be considered if a break in surgical technique occurs or a perirenal hematoma develops.
Nephrectomy

Nephrectomy is the surgical treatment of choice for unilateral hydronephrosis, abscessation, neoplasia, ureteropelvic polyp, and ectopic ureter. Severe cases of unilateral obstructive ureterolithiasis or nephrolithiasis may also require nephrectomy.

Unilateral right nephrectomy is performed through a right 16th or 17th rib resection or, alternatively, at the 16th and 15th intercostal spaces. Depending on the degree of anatomic variation, the most cranial approach can create a plane of dissection across the dorsal aspect of the costophrenic angle and through the diaphragm to the kidney. Although transthoracic approaches have been used successfully, they are more complicated than the right 17th rib resection and are not recommended.

In the transcostal approach, the animal is anesthetized, placed in lateral recumbency, clipped, and prepared for aseptic abdominal surgery. A 30- to 40-cm skin incision is made over the 16th or 17th rib. Dissection is continued deep to divide the musculature and expose the rib. The periosteum is incised and elevated around the rib, taking care to avoid injury to the intercostal vasculature. The rib is transected 2 to 5 cm distal to the costovertebral articulation using a bone saw, Gigli wire, or an osteotome (Fig. 70-6). Ventrally, the rib is disarticulated at the costochondral junction. Proximally, the ends of the parent bone are smoothed with a bone rasp. The medial costal periosteum is longitudinally incised, and the kidney is exposed by blunt dissection through the retroperitoneal fat. If additional exposure is required, the incision can be extended ventrally.

The kidney is mobilized by digital circumferential dissection through perinephric fat to expose the ureterovascular pedicle and penetrating capsular vessels (Fig. 70-7). Small capsular vessels and accessory renal arteries are electrocauterized and ligated, respectively. The ureterovascular pedicle is isolated, and the artery, vein, and ureter are individually double-ligated (Fig. 70-8). The use of hemostatic vascular clips or staples facilitates removal of the kidney and provides adequate access for suture ligation of major vascular elements.

After removal of the affected kidney, the renal fossa is lavaged and again evaluated for evidence of hemorrhage. The ureter is mobilized, ligated as far distally as possible, and transected. (Resection of the pelvic ureter is not possible when using a flank approach for nephrectomy.) Either Penrose or closed suction drains are placed after resection of the kidney to evacuate blood accumulating in the dead space or to manage urine-contaminated tissues.

The periosteum of the rib and deep fascia are closed with a synthetic absorbable suture material placed in simple-interrupted fashion. The subcutaneous tissues and skin are closed routinely. Unilateral left nephrectomy of the horse is performed in similar fashion using either a 17th or 18th rib resection or a dorsal flank incision.
The standing horse. Preparation of the horse for this surgical technique has been described for the left kidney in 1997. The hand-assisted laparoscopic procedure holds promise, it is technically demanding and accessory renal arteries. It should be noted that while the Complications include pneumothorax and bleeding from prior to making a small flank incision to retrieve the kidney. Company, Germany) are used to ligate the renal artery, vein, and ureter, in that order. The area is checked for hemorrhage clockwise) laparoscopic ligation instruments (Richard Wolf to identify the vessels. Specialized (clockwise and counter- contralateral to the peritoneal cavity. The peritoneum is sharply incised via an instrument portal and then bluntly, manually dissected to expose the left kidney. Careful manual dissection is used to completely identify all of the vascular structures entering and leaving the kidney. The renal artery and vein are double-ligated, separately using no. 2 polyglactin 910 with one-handed ties. The vessels are transected and the kidney is delivered out of the flank incision. The ureter is double-ligated and the incisions are closed routinely.

The most immediate and severe complication is uncontrollable hemorrhage, which generally originates from a torn accessory branch of the renal artery. Benefits from hand-assisted procedures include: smaller surgical incision, decreased surgical time, and less surgical morbidity, in addition to eliminating the need for general anesthesia. Although this procedure has not been applied clinically on a large scale, the procedure holds significant promise.

Laparoscopic Nephrectomy by Hand-Assisted Techniques

Laparoscopic nephrectomy in the horse has been described. An ipsilateral flank approach is used for removal of the respective kidney. At least three portals are required: the first between the 17th and 18th ribs ventral to the tuber coxae, and the second and third in the paralumbar fossa caudal to the 18th rib. A 0-degree laparoscope is utilized. The procedure for removal of the left kidney starts with injection of epinephrine (1 mg in 10 mL of saline) in three or four sites at the dorsal border of the spleen to create splenic contraction. The perirenal fascia is injected dorsally with 20 mL of 2% mepivacaine. An electrocautery hook blade is used to create a plane of dissection dorsal to the kidney. Perirenal fat is dissected and removed with curved laparoscopic scissors. The hilus of the kidney is carefully dissected to identify the vessels. Specialized (clockwise and counterclockwise) laparoscopic ligation instruments (Richard Wolf Company, Germany) are used to ligate the renal artery, vein, and ureter, in that order. The area is checked for hemorrhage prior to making a small flank incision to retrieve the kidney. Complications include pneumothorax and bleeding from accessory renal arteries. It should be noted that while the procedure holds promise, it is technically demanding and requires practice before attempting it on clinical patients.

The first hand-assisted nephrectomy in human medicine was described in 1997. The hand-assisted laparoscopic surgical technique has been described for the left kidney in the standing horse. Preparation of the horse for this surgery includes withholding feed for at least 12 hours, and administration of perioperative antibiotics and analgesics. The left paralumbar fossa is clipped and surgically prepared for aseptic surgery. Administration of a systemic α2-agonist provides sedation, and local infiltration with mepivacaine provides anesthesia. Because of the open approach, insufflation of the abdominal cavity is not necessary. A 10- 12-cm skin incision is made in the paralumbar fossa beginning 5 to 8 cm below the dorsal border of the internal abdominal oblique muscle. The external abdominal oblique muscle is sharply incised and a modified grid approach is used to gain access to the peritoneal cavity. The peritoneum is sharply incised. A laparoscopic viewing portal is made dorsal to the proximal border of the flank incision, and an instrument portal is created dorsal and cranial to the viewing portal.

A 0-degree laparoscope is utilized for viewing the surgical site, and a hand within the abdomen is used for retraction and blunt dissection. The retroperitoneal space caudal to the kidney is infiltrated with 15 to 20 mL of mepivacaine followed by digital massage to facilitate distribution. The peritoneum is sharply incised via an instrument portal and then bluntly, manually dissected to expose the left kidney. Careful manual dissection is used to completely identify all of the vascular structures entering and leaving the kidney. The renal artery and vein are double-ligated, separately using no. 2 polyglactin 910 with one-handed ties. The vessels are transected and the kidney is delivered out of the flank incision. The ureter is double-ligated and the incisions are closed routinely.

The surgical approach for nephroptomy is similar to that used for nephrectomy. The procedure is technically difficult, given the depth and dimensions of the surgical field and the reduced intraoperative visualization of the tissues, complicated by hemorrhage from the penetrating capsular vessels. In canine patients, the approach is through a longitudinal sagittal incision in the convex lateral surface of the kidney. To make such an incision, the kidney must be dissected free from the perirenal fat. This disrupts multiple small penetrating capsular vessels that require hemostasis.

Canine nephroptomy incisions are closed by gently pressing the renal halves together with sustained pressure.
However, capsular sutures or parenchymal mattress sutures should be considered for closure of the equine kidney. Although pyelotomy has been suggested as a reasonable approach to the canine renal pelvis, its small size increases the risk of accidental transection of an interlobar artery. Likewise, the close proximity of the renal artery and veins would make pyelotomy a difficult and risky procedure to perform in equine patients.

**Ureterotomy**

Indications for ureterotomy in the horse are limited principally to obstructive urolithiasis. Presentation of uncomplicated cases of ureteral calculi for surgical treatment is rare. Horses are often chronically affected and have developed some degree of renal pathology. Some horses with sufficient renal mass remain asymptomatic, and the condition is diagnosed at necropsy as an incidental finding.

Horses with identifiable ureteral pathology may be explored through a flank laparotomy, or through caudal ventral midline laparotomy in the mare. Exposure is difficult and extremely limited over the posterior course of the ureter. Typically, lesions are located in the proximal third of the ureter. When lesions can be identified and exposed, the ureter is incised proximal to the obstruction, and the contents are evacuated with surgical suction. The urolith is removed and the ureter closed in a simple-continuous pattern with synthetic absorbable sutures. Silastic tubing may be introduced into the ureter as a stent over which the ureteral repair may be performed. When direct surgical intervention is not possible, the use of a grasping basket (Dormia Stone Dislodger, V. Mueller Company, McGow Park, Ill) can facilitate closed dislodgment of a urolith.43 The instrument is introduced into the ureteral orifice by direct insertion (mares) or under videoendoscopic control using a perineal urethrotomy (males) (see Chapter 72). Guidance by rectal palpation is desirable to manipulate the dislodger into a position proximal to the urolith. The dislodger is subsequently opened and retracted to ensnare the urolith and displace it distally using slow, gentle traction.

Repair of ureterorrhesis is approached in similar fashion.23,24 In a case report, successful repair of a traumatic ureteral tear in a postpartum mare was accomplished with an indwelling polyethylene stent tubing (outside diameter, 1.90 mm).23 The salient presurgical features of the case included profound uropertoneum and associated electrolyte abnormalities (hyponatremia, hyperkalemia). A ventral midline celiotomy was utilized; however, because of the accumulation of urine around the ureter and broad ligament, the rent within the ureter could not be identified for primary repair. The surgery was assisted with the use of videoendoscopy of the urinary bladder. This allowed the surgeon to accurately place the stent within the ureter past the presumptive location of the rent. The stent was checked for urine production and then anchored to the vaginal mucosa and perineal skin and kept in place for 21 days. Although a few prosthetic constructs are available for use as ureteral stents in human medicine, the optimal size (no. 7 to 9 French in humans) and material have yet to be determined for the horse and will likely not be determined scientifically because of the rarity of the condition.

**Neoureterostomy**

Neoureterostomy techniques are used in the horse to manage ectopic ureters. In human and canine patients, vesicoureteral anastomosis has traditionally been the method of choice for treatment of ectopic ureters and selected cases of ureteral avulsion. Complications with these techniques in equine patients prompted treatment of foals by unilateral nephrectomy, assuming that the contralateral kidney was normal.16,17 Surgical success can be obtained, however, in large horses.

The surgical approach is made through a caudoventral midline incision, extended to the pubis for exposure of the bladder. The viscera are packed off cranially in the abdomen, and the ureter is identified as it traverses the dorsolateral bladder. The ectopic ureter can be identified by retrograde catheterization. If the ectopic ureter is in close proximity to the dorsal bladder, a side-to-side or end-to-side extravesicoureteral anastomosis may be performed to create a new ureteral opening along the dorsolateral cranial base of the bladder. The distal ureter is ligated and dissected free unless it is in an intramural location and surgically inaccessible.

Alternatively, if the ectopic ureter is not in close proximity to the bladder, the ureter may be ligated distally and neoureterostomy achieved by intravesicoureteral anastomosis (Fig. 70-9). Tunneling the ureter creates a functional equivalent of a distal ureteral valve, which reduces the likelihood of vesicoureteral reflux.44 Apposition of the ureteral and vesicular mucosa with small (3-0, 4-0) synthetic absorbable suture material is ideal (Fig. 70-10).

![Figure 70-9. Ligatures are placed to secure a ureter (arrow) after translocation to the bladder from an ectopic site. The ureter has been tunneled through the seromuscular layer of the bladder to prevent vesicoureteral reflux. (Courtesy Candace Lundin, DVM.)](image-url)
Aftercare

After all renal surgery, horses should be evaluated for water consumption and urine production and supported with intravenous fluids. Serum electrolytes and clearance ratios may reveal transient imbalance in electrolyte clearance after nephrectomy, particularly with regard to potassium. Fluid therapy should be adjusted accordingly.

Prophylactic antibiotics are indicated during the perioperative period because this is a clean-contaminated surgery. When septic conditions are encountered, antibiotic therapy should be directed by the results of intraoperative culture and sensitivity analysis. When potentially nephrotoxic antibiotics must be used, dosages should be adjusted for the reduction in renal mass. Depending on the drug, serum levels can be monitored for peak and trough levels to minimize the possibility of renal damage.35

Complications

The patient should be monitored for the development of pneumothorax during surgical dissection. Although inherently a part of the transthoracic approach, pneumothorax can develop when a flank approach using rib resection disrupts the crura of the diaphragm. Access to a mechanical ventilator may be required immediately in the event that the pleural space is opened during the flank approach to the kidney.34

Other complications of renal surgery include postoperative hemorrhage and infection. Management of postoperative hemorrhage is based on prevention through application of good surgical technique for isolation and cautery or ligation of contributing and emerging vessels. Assessment of packed cell volume and coagulation defects is appropriate before undertaking renal biopsy or excisional techniques. Surgical drainage is appropriate whenever diffuse hemorrhage, seroma, or bacterial contamination is anticipated.

Bladder
James D. Lillich

Richard M. DeBowes

ANATOMY AND PHYSIOLOGY

The equine bladder is a pear-shaped organ free at its apex and supported at its base by paired lateral ligaments and a ventral median ligament.1 Within the free margins of the lateral ligaments of the bladder, fibrous remnants of the umbilical arteries remain as the round ligaments of the bladder. Distention of the bladder results in cranial displacement of the apex to a position cranial and ventral to the pubic bone,1 and this displacement may be found on either side of the ventral midline.

The urinary bladder is the storage organ of the urinary tract and has a large capacity. It is composed of two interwoven layers of smooth muscle and lined with transitional epithelium supported by a thick, compliant submucosa.1,2 The inner layer of muscle is oriented in a circular fashion and the outer muscular layer is oriented longitudinally, except over the dorsal cranial bladder, where the circular layer is external.2 The importance of this anatomic difference is considerable, because when perinatal cystorrhexis occurs, the bladder commonly ruptures in this dorsal cranial region.3,4 A small amount of disorganized scar tissue is located at the ventral cranial bladder, a remnant of the fetal urachus.

The urachus is a tube-shaped organ responsible for the conduction of urine from the primitive embryonic bladder through the umbilical cord to the allantoic sac. On separation of the umbilical cord shortly after parturition, the urachus degenerates along its intra-abdominal course and is replaced by fibrous tissue.

DISORDERS REQUIRING SURGERY

Pathologic conditions affecting the equine bladder that are amenable to surgical intervention include cystorrhexis,2-25 persistent urachus,5-6,15,17,26-28 cystic calculus,6,16,29-47 eversion,48 and transitional cell carcinoma.6 Cystorrhexis and persistent urachus are the most common indications for surgery of the bladder and typically affect young or newborn foals. Cystic calculi and neoplastic diseases are less commonly observed and usually affect only adult horses. Eversion of the bladder occurs exclusively in females.

Uroperitoneum

Uroperitoneum is a serious condition that results in the development of uremia and severe electrolyte and acid–base imbalances.3,5,18 Although uroperitoneum is the result of urinary bladder rupture, a variety of congenital or traumatic defects of the proximal urinary tract are reported.49,50 Rupture of the foal’s bladder occurs because of congenital defects2-5 or compressive forces associated with parturition.3-5 The rupture occurs along the dorsal or dorsiocranial margin of the foal’s bladder (Fig. 71-1) because of the inherently thin wall in that area.2 With less frequency, cystorrhexis has also been diagnosed in adult horses with uroperitoneum,7-9,31 and it may be secondary to obstructive disease of the urethra.
region.3,4 A small amount of disorganized scar tissue is the bladder commonly ruptures in this dorsal cranial is considerable, because when perinatal cystorrhexis occurs, the inner layer of muscle is oriented in a circular fashion and the outer muscular layer is oriented longitudinally, except over the dorsal cranial bladder, where the circular layer is external.2 The importance of this anatomic difference is considerable, because when perinatal cystorrhexis occurs, the bladder commonly ruptures in this dorsal cranial region.3,4 A small amount of disorganized scar tissue is located at the ventral cranial bladder, a remnant of the fetal urachus.

Andrew T. Fischer, Jr.
Richard M. DeBowes

Foals 1 to 5 days old are affected. Although the majority are male, the problem may also occur in females. Foals are initially normal in clinical appearance and usually become symptomatic by 1 to 3 days of age. Clinical signs include depression, progressive anorexia, and abdominal distention with mild to moderate colic. Some foals that experience severe abdominal distention become dyspneic. Affected foals are capable of voiding a stream of urine, although increased frequency and reduced volume of urine flow can be expected.

The diagnosis of uroperitoneum is suspected from the history and findings on physical examination. Confirmation of the diagnosis of uroperitoneum in foals of all ages can usually be achieved through abdominocentesis, as well as through dye studies, contrast radiography, ultrasonography, and cystoscopy.

Clinicopathologic evaluation commonly reveals evidence of marked hyperkalemia, hyponatremia, and hypochloroemia. Dehydration and metabolic acidemia are commonly observed, particularly in older foals. Although serum and peritoneal creatinine and urea nitrogen values are often elevated, creatinine is the most meaningful parameter to evaluate.

Peritoneal fluid from affected individuals has a variable volume of a clear, yellow, odorless fluid with a low specific gravity (less than 1.008). Urinary calcium carbonate crystals have been identified on microscopic evaluation of fluid harvested by abdominocentesis, but this finding would not be typical in foals with uroperitoneum.

Sterile solutions of methylene blue, fluorescein, or neoprontosil may be instilled into the bladder of foals suspected of having uroperitoneum secondary to cystorrhexis. Identification of instilled dye in abdominal fluid recovered from drains or abdominocentesis confirms the diagnosis.

Alternatively, a lateral abdominal radiographic examination after retrograde contrast medium instillation (Renografin-76, Squibb Diagnostics, New Brunswick, NJ) into the bladder identifies the presence of a rupture (Fig. 71-2). Cystoscopic examination of the bladder is valuable for identification of bladder ruptures in adult horses. Its value in foals is limited by the sex of the foal and the size of the endoscope. Ultrasonographic examination may also be used to identify a rent in the urinary bladder. In addition, a "bubblegram" (sterile saline shaken and instilled into the bladder during the ultrasonic examination) can confirm the existence of a rent (see Fig. 69-3).

Foals with uroperitoneum must be medically stabilized before anesthetic induction and should be examined for the presence of concurrent disease. Dehydration should be managed by the administration of 0.9% or 1.8% to 2.5% sterile saline for dehydrated or rehydrated foals, respectively. Foals with moderate to severe abdominal distention may require peritoneal drainage to improve their cardiovascular and ventilation status. Correction of pre-existing electrolyte abnormalities is important, particularly of hyperkalemia, which is arrhythmogenic. Drainage of the peritoneal urine or peritoneal dialysis with concurrent volume expansion and supplementation of sodium chloride and bicarbonate should be sufficient. Supplementation of serum sodium levels is important because hyponatremia potentiates the cardiotoxicity of hyperkalemia. Once stabilized, affected individuals are managed by midline celiotomy for abdominal exploration and cystorrhaphy (see "Cystorrhaphy," p. 881). Severely debilitated patients are suboptimal candidates for general anesthesia. Foals with uroperitoneum because of small tears in the bladder wall can be managed conservatively by medical support and closed continuous suction drainage of the bladder. Likewise, adults with uroperitoneum from bladder leakage secondary to obstructive urolithiasis have been managed with perineal urethrotomy and temporary urine diversion with a Foley catheter. This management should be considered a viable option when no definitive tear is appreciated on cystoscopic examination.

*References 3, 4, 12, 17, 18, 22.
Persistent or Patent Urachus

Persistent or patent urachus is a condition of young foals in which the urachus fails to close spontaneously at or shortly after parturition. The pathogenesis could be either excessive traction on the umbilicus as a congenital problem or the development of omphalophlebitis as a contributing postnatal problem. Patent urachus has been associated with development of septic arthritis, septic physitis, and septicemia complex. Streptococcus species, Actinobacillus species, and Escherichia coli have been implicated in septicemic extensions of umbilical infections.

Affected foals show moisture around the navel region (Fig. 71-3). Some foals drip or stream urine from the umbilicus when posturing to urinate. In chronic cases, urine scald may be present around the navel. Foals should be evaluated for the presence of a complete and patent urethra. Foals with septic omphalophlebitis may have grossly enlarged navels (Fig. 71-4) and purulent drainage associated with the urachal fistula. When deep urachal infection is present, as determined by bacterial culture and sensitivity tests, systemic antibiotic therapy should be initiated. If the foal develops symptoms consistent with septicemia, further evaluation and application of additional therapies, including surgery, are warranted.

The diagnosis of persistent or patent urachus is frequently assumed from the history and findings on physical examination. Positive-contrast radiographic examination confirms the presence of a patent urachus by documenting the clearance of contrast agent through the urachus after retrograde cystography. Foals suspected of having urachal disease or omphalophlebitis should be evaluated by ultrasonographic examination. Identification of vesicourachal patency is confirmatory, and identification of an umbilical or urachal abscess necessitates prompt surgical intervention.

Most uncomplicated cases of congenital patent urachus are treated medically by systemic antimicrobial therapy and topical application of cauterizing or astringent compounds such as phenol, Lugol’s iodine, or silver nitrate. Foals with uncomplicated congenital patent urachus typically respond after a few days of therapy. If resolution has not occurred after 5 to 7 days of treatment, surgical therapy is recommended.

Individuals requiring surgical management are operated on through a modified midline celiotomy for exploration, evaluation, and resection of the urachus with its associated...
Urolithiasis

Urolithiasis is a potentially serious but relatively uncommon disease of horses.\(^6,16,29,47,56-59\) Renal,\(^56,57,60\) ureteral,\(^15,33,47,56\) urethral,\(^54,61\) and cystic calculi\(^33,45,47,56\) all can occur, but cystic calculi are the most common. The etiopathogenesis of urolithiasis has not been thoroughly defined. A dietary etiology has not been demonstrated. Mineral content of urolithiasis has not been defined. A dietary etiology has not been demonstrated. Mineral content of urolithiasis has not been thoroughly defined. A dietary etiology has not been demonstrated. Mineral content of urolithiasis has not been thoroughly defined. A dietary etiology has not been demonstrated. Mineral content of urolithiasis has not been thoroughly defined. A dietary etiology has not been demonstrated. Mineral content of urolithiasis has not been thoroughly defined. A dietary etiology has not been demonstrated. Mineral content of urolithiasis has not been thoroughly defined. A dietary etiology has not been demonstrated.

Urine scald dermatitis of the adductor surfaces of the hindlimbs is common in chronically affected horses. Patients may vocalize while urinating, however, intermittent abdominal discomfort is more commonly associated with calculi of the upper urinary system.\(^6,62\)

Diagnosis is made from the history and findings on physical examination, supported by a rectal examination. Palpation of the bladder is definitive for diagnosing cystic urolithiasis. A cystoscopic examination provides additional information on the number and type of stones, the patency of the ureters, and the presence and severity of traumatic cystitis.\(^47,63\) A variety of surgical approaches have been suggested for removal of cystic calculi.\(^1\) Laparocystotomy is the treatment of choice for removal of the calculus after effective cleansing and evacuation of the bladder\(^15,16,37-44,47\) (see "Cystotomy," p. 881).

Electrohydraulic lithotripsy or mechanical crushing offers an alternative therapeutic approach.\(^18,59\) Male patients may be sedated, blocked (epidural), and prepared for a standing perineal urethrostomy (see Chapter 72). The bladder is emptied and the calculus identified by cystoscopy. A lithotripsy probe (Electrohydraulic Lithotripter, Richard Wolf Medical Instruments Corp, Rosemont, Ill) or lithotrite is passed through the urethrostomy into the bladder. Electrical current is applied to the calculus to produce fragmentation. Pieces of the calculus may be removed by grasping forceps or by warm sterile saline lavage. Perioperative complications include stricture with fibrosis and urethral diverticulum formation.\(^64\) In female patients, calculi can be removed manually through the urethral sphincter or with the aid of sphincterotomy. Large calculi may require mechanical crushing before removal.

Shockwave, dye-pulsed, and holmium:yttrium-aluminum-garnet (holmium-YAG) laser lithotripsy have also been reported.\(^64-66\) Detailed descriptions are available, and the techniques have merit for providing surgical resolution of the clinical signs with mild surgical morbidity. Although these applications minimize surgical trauma over conventional surgical approaches, the availability and expense of the equipment limit large-scale use. Additionally, failure of the holmium-YAG laser to completely pulverize the cystic calculi has been reported.\(^66\)

Bladder Eversion

Bladder eversion may occur in the female horse.\(^48\) It is associated with parturition and third-degree perineal lacerations. Diagnosis is made on the basis of the history and physical examination findings. Typically, the bladder is everted through the urethral sphincter, so that exposed mucosa extends beyond the ventral commissure of the vulva (Fig. 71-7). Visceral contents can be contained within an everted bladder. Manual reduction followed by pursestring suture placement around a Foley catheter is the treatment of choice. In chronic cases, however, the exposed bladder

---

Figure 71-6. The type I urolith is readily recognized by its spiculated appearance and yellow-green color.

---

\(^1\)References 6, 15, 16, 31, 32, 47.
mucosa can become edematous and necrotic, requiring partial cystectomy. Partial cystectomy can be accomplished in a standing patient with sedation, epidural anesthesia, and incremental resection of the diseased bladder. Care should be taken to identify and exclude the ureteral openings from surgical manipulation.

Neoplasia
Neoplasia of the equine bladder is rare but includes squamous cell carcinomas, transitional cell carcinomas, leiomyomas, and leiomyosarcomas, with squamous cell carcinomas being the most common. Clinical signs include hematuria and stranguria. Solitary lesions of the apex of the bladder may be amenable to resection cystoplasty. Disseminated lesions have probably developed beyond the point where surgical management would be effective.

SURGICAL PROCEDURES
Cystorrhaphy
Cystorrhaphy is indicated for disruption of the bladder. The anesthetized patient is positioned in dorsal recumbency. An appropriate-size rubber catheter (Sherwood Medical Industries, St. Louis, Mo) is passed through the urethra and secured in the bladder to ensure outflow of urine and to permit intraoperative lavage of the base of the bladder. The prepuce in males is cleansed and closed with suture or towel clamps to reduce the possibility of incisional contamination. The abdomen is aseptically prepared for a ventral midline incision.

In the adult female patient, the surgeon should make a 15- to 18-cm caudal midline incision that extends caudally from a point 2 to 5 cm cranial to the umbilicus. In foals, the incision should be directed abaxially to create an elliptical incision around the umbilicus for removal. In the male patient, the cranial aspect of the incision is identical; however, the skin and subcutaneous layers of the caudal incision should be directed 2 to 4 cm paramedian to the prepuce (Fig. 71-8). The prepuce can be mobilized and retracted to expose the posterior midline for deep incision.

After the peritoneal cavity has been opened, peritoneal fluid should be cultured and suctioned. The bladder is exposed by maintaining traction on the urachus if present (Fig. 71-9). Large, self-retaining retractors (Balfour, Finochietto) may be used to facilitate the abdominal exploration. The bladder and urachus should be inspected to identify the site of rupture. The site of rupture in the foal may be the urachus as well as the dorsal or ventral bladder (Fig. 71-10). Urachal rupture is a sequela of urachal infection, especially in septicemic foals (Fig. 71-11). Ventral tears run longitudinally along the ventral bladder to the neck, making surgical access difficult.

If the origin of the uroperitoneum is not evident, the bladder may be distended by retrograde introduction of a sterile solution of fluorescein or methylene blue through the urethral catheter. This method identifies thin or attenuated areas in the bladder wall that may be leaking, typically on the dorsocranial surface of the bladder.
Once the tear is identified, the wound margins are débrided (Fig. 71-12). Culture and histopathologic evaluation of the débrided margins of the tear in septic foals should be considered. The use of monofilament stay sutures to support the bladder during primary repair is recommended. Surgical closure of the tear should be accomplished in two layers: an interrupted pattern in the first layer, followed by a continuous inverting pattern (Fig. 71-13). Small-size (2-0, 3-0) synthetic absorbable suture (chromic catgut, polyglycolic acid, polyglactin 910, or polydioxanone) on a taper-point atraumatic needle is used. Care should be taken to avoid suture penetration of the vesicular mucosa, because when sutures penetrate the bladder mucosa (of rabbits) in the presence of alkaline urine, the result is the formation of cystic calculi.

After repair, the bladder should be distended with sterile saline to evaluate for leakage along the suture line. In a young foal in which the urachus is present, the urachus should be resected, cultured, and removed with the umbilicus after primary repair of the tear (see “Cystoplasty,” p. 883). Before abdominal closure, the peritoneal cavity is lavaged with warm sterile saline solution. Indwelling drains (Argyle Trochar Catheter, Sherwood Medical Industries, St. Louis, Mo) may be placed if septic processes are present or anticipated. Despite the irritative nature of urine, clinically significant peritonitis is rare unless concurrent septic disease processes such as omphalophlebitis or neonatal septicemia are present. The midline incision is closed with no. 1 or no. 2 synthetic absorbable suture placed in simple-continuous fashion. The subcutaneous tissues and skin are closed with 3-0 synthetic absorbable sutures and skin staples, respectively.

Urinary bladder repair in the standing postparturient mare can also be accomplished by prolapsing the bladder either through a vaginal incision or urethrotomy and sphincterotomy. Clinical signs are consistent with uroperitoneum and diagnostic tests confirm the presence of a rent. Horses should be stabilized and the uroperitoneum, which is usually profound, sterilely drained. Caudal epidural anesthesia is utilized. For the vaginal approach, a rigid urinary catheter is placed to identify the location of the urethra and bladder under the vaginal mucosa. A 2-cm incision is made 5 to 10 cm caudal to the cervix. Blunt dissection increases the size of the incision, which facilitates the delivery of the bladder into the vaginal vault. Alternatively, a linear urethrotomy and sphincterotomy can be performed. A 5-cm incision is made in the urethral sphincter on the dorsal midline.
surgeon places a hand in the bladder and everts the bladder out of the vulva. Care is taken to identify the ureter openings. Rents are closed with a single- or double-layer closure. The bladder is replaced and the vaginal incision or sphincterotomy closed in a simple-continuous pattern with absorbable 2-0 or 0 suture material.

**Cystoplasty**

Cystoplasty is the technique of choice for patent or persistent urachus. Before anesthesia induction, the bladder is catheterized and emptied. The foal is anesthetized, prepared, positioned, and draped as described earlier (see "Cystorrhaphy"). If the urachus is open and draining, the margins may be oversewn with a continuous inverting suture pattern before aseptic preparation.

A 15-cm caudoventral midline incision is made. The incision extends caudally from a point 8 cm cranial to the umbilicus. An elliptical incision is created at the umbilicus for its removal. In male patients, the posterior aspect of the skin and subcutaneous incisions are directed 2 to 4 cm lateral to the prepuce (see Fig. 71-8). The prepuce can be mobilized and retracted to expose the posterior midline for deep incision.

The umbilicus and urachus are dissected free from the body wall. The falciform ligament and umbilical vein are ligated and resected as far cranial as possible. Occasionally, the midline incision must be extended cranially to permit adequate resection of the umbilical vein. The affected urachus may be thickened and distorted (Fig. 71-14). Adhesions may exist between the urachus or its associated vascular structures and the surrounding viscera. Care should be taken to identify and transect adhesions that involve the urachus before manipulation of the bladder.

Exposure of the bladder is achieved by sustained traction on the urachus. Traction should be applied with caution because of the friable nature of the tissue and the possibility of rupture. Sterile moistened laparotomy pads are used to pack off intestines and assist in positioning the bladder. Stay sutures are placed at the ventrolateral margins of the bladder for additional support and control of the bladder after resection of the urachus. The umbilical arteries (around the ligaments of the bladder) are ligated with a transfixing suture at the level of urachal resection.

An occluding forceps is used to isolate the urachus and apex of the bladder (Fig. 71-15). A transverse incision is made across the apex of the bladder to remove the urachus and vesicular apex (see Fig. 71-15). The urachus is removed and submitted for culture and sensitivity tests. Traction is applied to the previously positioned stay sutures to elevate the apex of the bladder and to prevent spillage of urine. Suction is used to remove the residual urine or pus from the bladder. Closure is accomplished using a two-layer inverting suture pattern with 2-0 or 3-0 synthetic absorbable suture material, taking care not to penetrate the lumen. Alternatively, a simple-continuous closure of the first layer may be followed by an inverting suture pattern. The abdomen is lavaged with warm sterile saline before closure. Unless significant spillage of urine or exudate has occurred, abdominal drains are not necessary. Broad-spectrum antibiotics are administered routinely for 3 to 5 days because of the potential for abdominal contamination from urachal bacterial contaminants.

**Cystotomy**

Cystotomy is the treatment of choice for cystic calculi. After anesthesia induction, the horse is positioned in dorsal recumbency. A urinary catheter is passed into the bladder and sutured in place. The prepuce is cleaned and sutured or closed with towel clamps. The abdomen is aseptically prepared for a ventral midline approach.

*References 6, 15, 16, 33, 38, 47.
A 20- to 25-cm skin incision is made along the caudal ventral midline of the abdomen. In male horses, the skin incision is directed lateral to the prepuce (see Fig. 71-8). With continued dissection of the subcutaneous tissues, the prepuce is mobilized and retracted to expose the posterior midline. The surgeon should identify and avoid the large superficial caudal epigastric and external pudendal vessels when dissecting deep to the prepuce to expose the posterior midline. In mares, the incision is made on the midline from the umbilicus caudally to the prepubic tendon.

The bladder is identified by palpation in the pelvic canal. Sustained gentle traction is required to exteriorize the bladder33,45,47 (Fig. 71-16). Once it is exposed, moistened laparotomy pads are used to pack off the bowel and elevate the bladder in the surgical field. Large-diameter stay sutures should be positioned at the ventrolateral aspects of the bladder to facilitate control of the cystotomy incision and to reduce urine spillage. A transverse incision is made across the ventral bladder to expose the urolith. Frequently, the urolith is closely adherent to the bladder mucosa, particularly in the case of a type I urolith. The mucosal layer of the bladder must be peeled back from the urolith to permit removal of the calculus (Fig. 71-17). After its removal, a full-thickness biopsy should be taken from the margin of the cystotomy incision for culture and histopathology. The bladder is lavaged extensively in an effort to remove small fragments of calciar material and blood clots. Irrigation of the bladder by retrograde introduction of sterile saline through the urinary catheter flushes small fragments of the urolith from the neck of the bladder toward the incision, where they can be evacuated through suction.

The cystotomy is sutured with a two-layer closure of synthetic absorbable suture material. Continuous inverting suture patterns such as the Cushing and Lembert patterns are preferred. The suture should not penetrate the urinary mucosa to the lumen. The bladder may be distended with sterile saline to evaluate the closure for leakage. The abdomen is lavaged with sterile balanced saline solution and suctioned. The midline incision is closed with no. 2 synthetic absorbable suture material in continuous or interrupted fashion. If the caudal limit of the incision was made in a paramedian location, the fascial closure is completed in two layers by suturing the deep and superficial layers of the rectus sheath separately. Of the two layers, the superficial sheath is the more critical to the security of the abdominal closure. The subcutaneous tissues and skin are closed in routine fashion.

**Parainguinal Approach**

Another surgical approach to the urinary bladder in the adult male horse has been described—the parainguinal approach.71 This approach eliminates the need to reflect the prepuce and reduces the chances of encountering large vessels prior to gaining access to the urinary bladder. With the horse in dorsal recumbency and the penis sterilely catheterized, the inguinal region is clipped and prepared for aseptic surgery. A 12- to 14-cm skin incision is made starting 2 cm cranial to the left external inguinal ring and continuing in a caudomedial direction toward the midline (Fig. 71-18). Subcutaneous tissues and fat are bluntly and sharply dissected to reveal the aponeurosis of the external abdominal oblique muscle. The aponeurosis is sharply incised, starting...
BLADDER 885

at the midline and continuing laterally roughly parallel to the skin incision for 12 to 14 cm. Retractor is used to gain access to the internal abdominal oblique muscle, which is separated along its fibers. The peritoneum is bluntly entered with the surgeon’s finger. The bladder is identified and exteriorized with steady traction. The surgical field can be isolated and the bladder twisted to maintain exteriorization to complete the cystotomy. Double-layer closure of the bladder is recommended. Closure of the abdomen is routine, with attention paid to the aponeurosis of the external abdominal oblique muscle. An interrupted cruciate, near-far-far-near, or a simple-interrupted pattern is recommended. None of the nine geldings that underwent this approach developed incisional complications, including herniation.

Laparoscopic Techniques

Laparoscopic techniques have been described for repair of cystorrhexis, persistent urachus, and umbilical infections in the foal.72,73 Patient preparation including appropriate diagnostic examinations and perioperative therapeutics do not differ from those used for foals undergoing conventional surgical approaches. Foals are placed in dorsal recumbency with the pelvic limbs elevated. This position usually demands that intermittent positive-pressure ventilation be available. The ventral midline is prepared routinely for aseptic surgery.

Because the foal’s body wall is thin, it is recommended that insufflation be done with a teat cannula and that lower (1 to 2 L/minute) insufflation rates be used. A 1.5-cm incision is made 5 cm lateral to ventral midline and 10 to 15 cm cranial to the umbilicus for placement of the laparoscopic cannula. A 30-degree laparoscope telescope is used to explore the abdomen. Additional portals are made 8 to 10 cm lateral and 5 cm cranial to the umbilicus.

For cystorrhexis, urine accumulation needs to be evacuated prior to insufflation. Once the telescope is placed, the entire bladder should be inspected. Two working portals are required to freshen the edges of the rent and repair the bladder with absorbable sutures using intracorporeal suturing techniques. It is prudent to test the bladder for leaks before deflating the abdomen.

For resection of umbilical remnants, or umbilical remnant infection, the umbilical vein and arteries are isolated with endoscopic scissors and dissected free to facilitate ligation. A large ligation clip or loop can be utilized. Several clips may be necessary to ensure proper ligation, especially when structures appear large or pathologic. Once the umbilical vein and arteries have been transected, an elliptic incision is made around the umbilicus through the body wall under laparoscopic guidance. The end of the bladder is exteriorized and resected. A two-layer closure in the bladder is recommended.

Closure of the body wall is routine. Closure of the portal is performed with no. 1 absorbable material in an inverted cruciate pattern in the external fascia. Intradermal sutures can complete the procedure. Overall, good visualization with minimal intervention is obtained with laparoscopic techniques. The use of nonabsorbable linear staples for repair of a tear in the bladder is discouraged, because the staples may serve as nidus for urolith formation.72

Laparoscopic techniques for removal of cystic calculi in the adult male horse have also been described.74 The horse is placed in dorsal recumbency with the pelvic limbs elevated. Additional preparation steps include placement of a urinary catheter and caudal retraction of the penis, the latter being secured between the patient’s legs. The bladder is lavaged and drained until clear saline irrigation solution is obtained.

A standard umbilical portal is made after insufflation. Five instrument portals are made to complete the procedure. The instrument portals are in a radiant line centered on the sheath. A laparoscopic electrocautery tip is inserted into the cranial right portal and is used for suction when the cystotomy incision is made. A retrieval bag is also placed in the abdomen, which is positioned below the bladder. The cystotomy incision is made just long enough to remove the calculus. A retractable metal loop forceps aids in the removal of the urolith and placement into the retrieval bag. Suction is used to remove residual debris. Closure of the bladder is accomplished with an auto-suture device. A double-layer closure is recommended. The bladder is tested for leaks prior to deflation of the abdomen. The umbilical portal is enlarged to retrieve the calculus within the retrieval bag. The linea and portal incisions are closed routinely.

Complications of this technique include intraoperative hemorrhage from the instrument portals, and obstructed visualization from falciform fat. It should be noted that practice is required to become proficient in using the auto-suturing devices. With proper preparation, cystic calculi can be removed safely and cleanly in the adult male horse.

Aftercare

Antibiotics are commonly administered after surgery of the bladder. In cases of cystorrhexis or persistent urachus, sepsis represents a risk,19 so antibiotics are routinely administered to reduce the risk of septic peritonitis and may be continued for several days or weeks postoperatively.17,18,27 In adult patients with urolithiasis, the risk of urine spillage during removal of cystic calculi is considerable.34,47 However, antibiotics are continued for only 48 to 72 hours unless clinical signs of infection develop.

Postoperative abdominal drainage is indicated if surgical findings suggest the presence of peritonitis or if gross soilage of the peritoneum from an urachal abscess has occurred. Generally, abdominal drainage is not required after cystorhaphy or cystoplasty. Unless significant spillage with fragments of uroliths has occurred, the need for peritoneal drainage in urolithiasis patients is not necessary. Patients with abdominal drains should remain on prophylactic antibiotic therapy.

Typically, patients are administered low doses of non-steroidal anti-inflammatory drugs to control postoperative and incisional discomfort. Patients recovering from cystorrhaphy and cystoplasty often require intravenous fluids to correct dehydration and acid–base and electrolyte imbalances. All patients should be routinely monitored for urine output after surgery. Foals that are at risk for sepsis or that are subjected to intensive medical care after surgery are candidates for development of gastric ulceration. Use of a type II histamine blocker (Zantac, Glaxo Inc, Research Triangle Park, NC) and a mucosal protectant (Carafate, Marion Labs Inc, Kansas City, Mo) is indicated in these cases.
Complications

Clinically significant complications of bladder surgery are rare. The most acute and striking complication is the development of severe ventricular arrhythmias in the anesthetized foal with uroperitoneum.\(^1\)\(^5\) Postoperative myositis resulting in death has also been documented.\(^7\) Correction of electrolyte and acid–base status before surgery minimizes the risk of developing these problems.

In foals, contamination of the peritoneal cavity with urine is common and may result in the development of chemical peritonitis.\(^8\) Although most foals with cystorhexis have a chronic history of uroperitoneum and presumably some degree of chemical peritonitis, the incidence of septic peritonitis is low\(^16\) unless concurrent septic omphalophlebitis or other septic processes are present simultaneously.\(^7\)\(^,\)\(^11\) In one retrospective study of celiotomy for the treatment of uroperitoneum, several foals had positive culture results for \textit{Mueller} and \textit{Candida} species.\(^18\) All foals with uroperitoneum and concurrent septic disease should be monitored closely for clinical evidence of septicemia or septic arthritis and physitis after surgery.

Adhesions have also been reported as a consequence of abdominal surgery in foals for correction of uroperitoneum.\(^18\) The development of septic peritonitis can result in an increased incidence of adhesion formation, particularly in the posterior abdomen near the bladder.\(^17\)

Contamination of the midline incision with urine or bacteria may lead to the formation of incisional edema and drainage. In adult male horses operated on for cystic calculi, preputial edema occurs occasionally.\(^47\) Although generally responsive to anti-inflammatory agents and local wound drainage, it may require temporary placement of periincisional drains. Surgical failures of the cystotomy incision after cystoplasty and exploratory cystotomy have been reported.\(^6\)\(^,\)\(^17\) Typically, these are not a problem.\(^19\)

REFERENCES

The urethra, a muscular tube lined by mucosa, serves as the normal conduit for urine flow to the exterior of the body after birth.1,2 In the mare, the urethra is 5 to 8 cm long and 2 to 3 cm wide, and it connects the caudal bladder to the cranial limits of the vestibule.1

The male urethra connects the bladder to the glans of the male penis and consists of pelvic and extrapelvic segments. The pelvic urethra is 10 to 12 cm long and expands to a width of 3 cm caudal to the prostate.1 Dorsally, the pelvic urethra receives the ducts of the seminal vesicles and the vas deferens in the paramedian diverticula lateral to the colliculus seminalis. Lateral and slightly caudal to the colliculus, numerous small ducts of the prostate enter the urethra. Distally, the ducts of the bulbourethral glands enter the pelvic urethra, arranged in two parallel rows of six to eight openings. The pelvic urethra and bulbourethral glands are enveloped in the urethritis muscle, which contracts to evacuate the urethra at the end of micturition or ejaculation. The pelvic urethra narrows caudally as it courses ventrally and distally, depending on the presence or absence of an erection. The extrapelvic male urethra is 1.5 cm wide and of variable length, depending on the presence or absence of an erection. The extrapelvic urethra courses distally through the male penis supported by the bulbospongiosus muscle and the corpus spongiosum penis to its distal limits, where it terminates at the glans as the urethral process.1

**PHYSIOLOGY**

The urethra functions as a conduit for the propulsion of urine distally during contraction of the detrusor muscle of...
the bladder. The urethra is enveloped in smooth muscle and is protected by muscular sphincters under voluntary and involuntary control. Since the urethra represents the only pathway for urinary outflow in the adult patient, its prolonged obstruction results in serious consequences, including cystostomy, uroperitoneum, and associated metabolic derangements.

Either a loss of neuromuscular control of the urethral sphincters or the presence of selected developmental anomalies can result in clinical urinary incontinence of urethral origin. Although it is not acutely life threatening, urinary incontinence can be a difficult problem to resolve, and it often is associated with ascending urinary tract infection.

**DISORDERS REQUIRING SURGERY**

Disorders of the equine urethra that require surgery are urolithiasis (primary urethral or secondary to cystic calculi), soft tissue obstructions (mucosal webbing), contusions, and lacerations. Traumatic injuries to the distal penis and urethra are the most common conditions. In stallions, kicks and self-trauma associated with fencing or housing commonly result in injury. Hematuria and hemospermia can also be considered disorders requiring surgery, because affected individuals may respond to temporary urinary diversion via perineal urethrostomy.

**Urethral Obstruction**

Acute urethral obstruction in the male horse results from occlusion with urinary calculi or, less commonly, from extramural compression associated with soft tissue problems of contusion, hematoma, stricture, parasitic granuloma, or neoplasia (see Chapter 66). Affected individuals may require temporary or permanent urinary diversion as part of their definitive therapy.

**Urolithiasis**

The etiology of equine urolithiasis is discussed in Chapter 71. Although large calculi can be accommodated by the bladder with few clinical signs, small (0.5 to 1.0 cm) calculi are capable of passing through the trigone and into the proximal urethra, occluding the equine male urethra and thus blocking urine outflow. The most common area of obstruction is at the junction of the wide pelvic urethra with the more narrow extrapelvic urethra. In contrast, mares rarely develop this condition because of the short length and wide diameter of the female urethra.

Horses demonstrate signs of moderate to severe colic related to distention of the urinary bladder, which must be differentiated from discomfort of intestinal origin. Horses with an obstruction assume the posture to urinate but pass little or no urine. Spontaneous urethral hemorrhage is commonly observed in these patients. Occasionally, affected individuals are refractory to analgesic therapy.

Close examination of the patient reveals a complete lack of clinical signs referable to endotoxemia. Tachycardia, tachypnea, and ileus may be observed but are probably the result of visceral discomfort associated with distention of the urinary bladder. Rectal examination reveals moderate to severe distention of the bladder. Passage of a rubber urinary catheter, a flexible urethral probe, or a fiberoptic endoscope identifies a urethral obstruction distal to the trigone (Fig. 72-1). Horses with the aforementioned history that become acutely asymptomatic should be suspected of having cystostomy and should be evaluated for uroperitoneum.

Medical treatment for urethrolithiasis includes sedatives, muscle relaxants, and analgesics, followed by attempted manipulation of the offending calculus. Caution should be used when selecting xylazine as a sedative because of its diuretic effect, which substantially increases the formation of urine. Phenothiazine-derivative tranquilizers have minimal diuretic effect, but their use in intact male horses may result in penile paralysis. Therefore, the use of sedation should always accompany the establishment of urinary outflow and bladder decompression. Distention of the urethra with a solution of sterile saline, sterile lubricant, and mepivacaine hydrochloride can facilitate ballottement of the calculus with a sterile urinary catheter. Temporary relief may be achieved with dislodgment and retrograde displacement of the obstructing urolith into the bladder, which permits the temporary evacuation of urine. Calculi managed in this fashion must ultimately be removed through either laparocystotomy or perineal urethrotomy. Calculi that cannot be dislodged retrograde in this fashion must be removed through perineal urethrotomy. Distally lodged uroliths may be removed by using laparoscopic or arthroscopic grasping forceps with the aid of endoscopic examination. Care should be taken not to further damage already irritated mucosa (Fig. 72-2).

**Obstructive Soft Tissue Lesions**

Obstructive soft-tissue lesions of the urethra are diagnosed infrequently. They include neoplasia, hematoma, and parasitic granuloma with the latter two conditions being most commonly observed.
Squamous cell carcinoma is the most frequently diagnosed neoplasm associated with the penis or prepuce of the horse. Although most of these problems are nearly unique to the male patient, squamous cell carcinoma of the mare’s perineum and vulva may extend to involve the extrapelvic urethra, typically in the region of the perineum. Large hematomas are capable of occluding the urethra until cystorrhexitis occurs. Hematomas are treated with rest and hydrotherapy. An alternative treatment regimen consists of draining the hematoma using an appropriate method for the specific case, or as dictated by the horse’s ability to urinate. Large hematomas that occlude or nearly occlude the urethra should be either drained or bypassed by temporary urinary diversion via perineal urethrotomy. Parasitic granulomas are readily managed by the administration of ivermectin or organophosphate pharmaceutical agents. Parasitic lesions respond to routine systemic therapy and rarely require surgical débridement. Affirmatively diagnosed neoplastic lesions are treated by local resection.

Urethrorrhexis, or urethral laceration, is observed periodically in horses after kicks or wire trauma involving the perineum or inguinal region. Urethrorrhexis is more difficult and requires either direct vision by urethroscopic examination or imaging by ultrasonographic examination. Confirmation of a diagnosis of closed urethrorrhexis is more difficult and requires either direct visualization by urethroscopic examination or imaging by positive-contrast radiographic or ultrasonographic examination. Retrograde distention of the urethra with sterile saline enhances its visualization and identification of its defect on ultrasonic examination. The literature suggests that in cases of suspected urethral trauma, radiographic confirmation is superior to urethral instrumentation (catheterization or urethroscopy).

Therapy is directed at controlling regional inflammation and diverting the flow of urine through a urinary catheter. The urethral epithelium has a relatively high potential for regeneration, and closed crushing injuries of the urethra

**Figure 72-2.** An endoscopic image of an obstructive type I urolith being removed from the distal urethra with a Ferris-Smith rongeur. (Courtesy Carolyn Arnold, DVM.)
may be treated by placement of a sterile urinary catheter for 5 to 7 days.\textsuperscript{5,8,25,28} Primary repair of a urethral laceration may not be necessary unless the urethra is completely transected.\textsuperscript{5,25} Inadvertent iatrogenic urethral transaction may not be appreciated for a few days. Urine accumulation within the scrotal tissues is usually evident. Repair of the urethra can be assisted with endoscopy and/or normograde passage of a urinary catheter through a perineal urethrotomy. Periurethral tissues should be débrided and the urethral mucosa apposed to reduce secondary-intention healing and stricture formation. With proper apposition of the mucosa, primary healing can be obtained with preservation of lumen diameter (Fig. 72-3).

### Hematuria and Hemospermia

Hematuria in geldings and hemospermia in stallions have been related to urethral defects that communicate with the corpus spongiosum penis. Linear urethral defects are identified with endoscopic examination, typically located at the level of the ischial arch. The origin of urethral defects is unknown. Treatment with temporary urethrostomy that does not enter the urethral lumen has been successful.\textsuperscript{29} This procedure is thought to lower vascular pressure of the corpus spongiosum penis during micturition. The technique, alone in the gelding and with sexual rest in the stallion, allows healing of the mucosal defect.

### SURGICAL PROCEDURES

#### Perineal Urethrotomy

Perineal urethrotomy is typically performed for temporary urine diversion in male patients with obstructive urinary outflow disease.\textsuperscript{*} In patients requiring chronic urinary diversion, a permanent urethrostomy may be created.\textsuperscript{29} For perineal urethrotomy or urethrostomy, the patient is sedated and confined in stocks for a standing surgical procedure.\textsuperscript{5,8,19} The administration of detomidine hydrochloride (Dormosedan, SmithKline Beecham, Lincoln, Neb) or a combination of xylazine (Rompun, Haver-Lockhart, Shawnee, Kan) and butorphanol tartrate (Torbugesic, Fort Dodge Laboratories, Fort Dodge, Iowa) is usually adequate. An epidural injection of mepivacaine hydrochloride (Carbocaine, Winthrop Laboratories, New York, NY) is administered to desensitize the perineal region. When epidural anesthesia is ineffective, the application of an inverted-V block is usually sufficient to desensitize the skin and superficial tissues of the perineal region. A rubber urinary catheter is advanced proximally through the urethra to aid in intraoperative identification of the urethra. The operative field is clipped and aseptically prepared for surgery.

A 6- to 8-cm longitudinal midline skin incision is made in the perineum extending from a point 10 to 15 cm ventral to the anus ventrally to the ischial arch\textsuperscript{5,8,19} (Fig. 72-4). The distal limit of the incision should not be located ventral to the ischial arch. The subcutaneous tissues are divided, and the longitudinal incision is continued deep to divide the bulbospongious muscle and corpus spongiosum.\textsuperscript{12,19} The urethra is exposed by retraction of these muscles. The urethra is identified and stabilized by palpation of the urinary catheter (Fig. 72-4, B). A longitudinal incision is made along the caudal surface of the urethra, and the mucosa is reflected abaxially. Intraluminal obstructions such as uroliths may be manipulated and removed by urinary catheters or forceps inserted through the perineal urethrotomy incision.\textsuperscript{12}

For temporary diversion of urine, the wound is managed with local care during the process of secondary-intention wound healing (Fig. 72-5). A urinary catheter may be placed through the temporary urethrotomy incision and secured with stay sutures for 2 to 4 days after surgery. Typically, a urethrotomy wound heals in 14 to 21 days with minimal complications.\textsuperscript{8} If a permanent urethrostomy is desired, the muscles of the ventral penis are sutured along their cut edges with a continuous suture of 3-0 synthetic absorbable suture to control hemorrhage. The urethral mucosa and skin are approximated using interrupted sutures of 2-0 or 3-0 synthetic monofilament nonabsorbable suture (Fig. 72-6). Care must be taken to ensure accurate, tensionless apposition of the perineal skin and urethral mucosa.

#### Distal Urethrotomy

Distal urethral calculi can be approached with grasping forceps with the aid of endoscopy. For uroliths that cannot be removed in this manner, a scrotal or prescrotal urethrotomy may be required. Horses must be anesthetized and positioned in dorsal recumbency. Technically, the surgical procedure is similar to that for perineal urethrotomy. If the lesion is sufficiently distal, a tourniquet may be applied to assist with hemostasis and improve intraoperative visualization. Incisions are made over or slightly proximal to the urethral calculus to permit the insertion of grasping forceps. After removal of the calculus, the incision is closed in anatomic fashion using 3-0 synthetic absorbable suture. It is important to accurately reconstruct the corpus spongiosum penis.

sum and bulbospongiosus muscle to reduce the risk for urine leakage and development of cellulitis. Approximation of the retractor penis muscle provides additional security for the closure.

Urethroplasty

The patient is sedated, restrained, and prepared for standing surgery as described. Repair of a urethral laceration is consistent with the repair of any other hollow viscus. Careful attention to wound débridement, lavage, and preservation of intrinsic vascular and neural supply is important. Fully circumferential lacerations may be repaired by end-to-end anastomosis. Fine (3-0) absorbable suture material such as polyglactin 910 (Vicryl, Ethicon, Somerville, NJ) should be used. The use of an intraluminal stent (urinary catheter) for the repair of a lacerated urethra is considered acceptable.28

Aftercare

After surgery of the urethra, the patient should be observed to ensure that urination occurs without difficulty. Antibiotics and nonsteroidal anti-inflammatory drugs may be administered as required. There is little need for prolonged postoperative analgesia. In cases in which urine was extravasated, the use of surgical drains is appropriate.29,30

The literature is unclear on the value of chronic catheter placement after urethral repair. Traditionally, catheters were left in place after primary repair of a traumatized urethra.31 More recently, chronic placement of urinary catheters has been discouraged because of locally increased inflammatory response and subsequent stricture formation.28 Postoperative stricture is minimized by limiting the duration of catheterization, by accurate tissue repair, by effective hemostasis, and by adequate drainage of the periurethral tissues.9,25 Because the chronic use of indwelling urinary catheters is controversial, they should be removed as soon as possible.6,19,26,30,31 Foley catheters may be secured in place with stay sutures during the first 48 to 96 hours. Foley catheters distended with saline or another salt solution are more easily tolerated than those distended with air.28

The potential for urine soilage of the ventral perineum and subsequent urine scalding is great. Care of the healing urethrotomy incision should include local cleansing for removal of accumulated urinary salts or exudate. The skin of the ventral perineum, inguinal region, and adductor surfaces of the hindlimbs should be cleansed daily and protective emollients applied.

Complications

Mild tenesmus and discomfort are expected after surgery. The effect of urine contamination of tissues is usually minimal unless tissue trauma is advanced or sepsis is present. Antibiotic and anti-inflammatory therapy is appropriate in such cases. Partial dehiscence of urethrostomy incisions occurs infrequently and may be managed with local tissue therapy, débridement, and delayed closure.9,25-27 Stricture of the urethra is a common postoperative finding; stricture is most commonly observed in distal urogenital surgeries such as posthioplasty or subtotal phallectomy.23 Surgical procedures involving the distal urethra may require spaturatation to reduce the likelihood of stricture formation (see Chapter 66).19,23,24 Less commonly, thin veins of urethral mucosa may form in such a fashion as to partially occlude the urethral lumen, requiring further surgical revision.12

REFERENCES

Lameness is a symptom and can be defined as an alteration of the normal gait pattern caused by a functional or structural disorder in the locomotor system. Clinicians assess lameness by mentally comparing the gait of the lame horse with movements of normal subjects, by matching the symmetry of movements of the left with the right body side, and by comparing the gait before and after an intervention such as a stress test or a diagnostic nerve block. Visual assessment carries all risks that are inherent in subjectivity, and therefore, interpretation of clinical signs depends directly on the expertise of the observer. Because gait compensations made by lame horses may occur very rapidly or subtly, the temporal resolution of the human eye can easily be overtaxed.

Quantitative gait analysis offers a higher spatial and temporal resolution and allows objective characterization of intermittent and mild lamenesses or of gait alterations involving more than one limb. The benefit of clinically applied gait analysis is the reliable documentation of individual locomotion patterns, the degree of lameness, and the result of diagnostic anesthesia, as well as being a quantitative assessment of drug efficacy and specific interventions such as shoeing or surgical procedures.

**METHODOLOGY**

Biomechanics involves the application of mechanical laws to living structures. Two complementary methods are used to study the body in motion: kinematics and kinetics.

**Kinematic Analysis**

Kinematic analysis measures the geometry of movement without considering the forces that cause the movement. The movements are quantified by linear and angular variables in relation to a timeline. The current techniques of choice are digital videography combined with commercial marker tracking software or opto-electronic systems (Table 73-1). Light-reflective markers are placed over specific bony landmarks or joint centers and filmed at 50 to 2000 frames per second (Fig. 73-1, A). In contrast to videographic systems where whole-image information is processed, opto-electronic cameras selectively record the marker points by emitting and capturing selected wavelengths of the light (e.g., in the infrared spectrum). Body-marker tracking is performed either manually or automatically and results in the two-dimensional coordinates of the marker’s center. A multi-camera setup (see Fig. 73-1, B) allows the reconstruction of the three-dimensional trajectory coordinates of the various body markers by merging numerous two-dimensional views using direct linear transformation (see Fig. 73-1, C).

By combining kinematic data with a segmental body model of a standard horse, the three-dimensional movement of the body center of mass (BCM) can be reconstructed. The BCM is a key factor in the analysis of equine locomotion, since its position and trajectory determine the distribution of loads within the limbs.

**Kinetic Analysis**

Kinetic analysis studies the forces that are responsible for a movement. Kinetics distinguishes between internal and external forces and torques. Human sensory perception is not able to derive kinetic information from visual gait assessment.

External forces—that is, the forces acting between the hoof and the ground (ground reaction force [GRF])—can be measured directly by using a force plate or a force shoe, or on a force-measuring runway such as the Equine Gait Analysis system. The most established technique is the force plate embedded in a runway. Standard force plates (see Table 73-1) are able to split the force vector into its three orthogonal components, the transverse-horizontal (Fx), the longitudinal-horizontal (Fy), and the vertical force (Fz) component. However, repeated recording sessions are necessary to obtain a sufficient number of representative strides of the different limbs. A treadmill equipped with a dynamometric platform combines the benefits of kinetic analysis with the advantages of the treadmill, such as control of movement velocity and data acquisition over multiple consecutive motion cycles of all four limbs simultaneously (Fig. 73-2). To achieve accurate gait analysis, since kinematic and kinetic parameters are known to be velocity dependent, the instrumented treadmill is fully operational in a clinical setup. Typically, up to 50 strides per limb, at both walk and trot, are recorded within less than 5 minutes. The calculation of the vertical force traces starts during data acquisition, and force curves are presented in real time on a computer screen. Fourteen force, and 11 temporal and 6 spatial parameters are
derived from the raw data and presented graphically a few seconds after completion of the measurement. This allows instantaneous assessment of diagnostic blocks (Fig. 73-3).

**Modeling of Movement**

Mathematical concepts that involve applying the dynamic laws of Newton and defining the body as a linked multisegment model provide a noninvasive way to study the forces within the body based on kinematic and kinetic data (inverse dynamics) or to simulate movement of a horse based on known forces (forward dynamics).

Inverse dynamic analysis is used to calculate the internal forces acting on the joints (joint moments) as well as tendon forces and bone strains. Tendon force and joint moment profiles of the distal limb have been established during stance and swing phase, during various gaits, and while jumping. In the stance phase dynamics of one limb, a static equilibrium is assumed between the external forces (represented by the ground reaction force vector) and the tendon forces acting on the limb joints. Radiography of the specific anatomic region supplies the geometric information (e.g., moment arm of the tendons at the coffin and fetlock joint). Kinematic measurements provide the joint angles and the position of the joint rotation centers in relation to the GRF vector. During the swing phase, in the absence of external forces, inertial parameters (mass, center of mass, moments of inertia) combined with the kinematic data permit the calculation of the power flow along the limb joints.

**Clinical Application of Gait Analysis**

The principal clinical application of gait analysis is the quantification of locomotor performance and lameness. The unloading of a painful limb will lead to a redistribution of load and to visible compensatory movements of specific body parts. Load redistributions are closely related to changes in stride timing and coordination between limbs.

**Kinematics of the Lame Horse**

In weight-bearing lamenesses, the most consistent changes are observed in the vertical displacement and maximal vertical acceleration of the head and sacrum, as well as in the maximal metacarpophalangeal (MCP) hyperextension and the maximal distal interphalangeal flexion angle. At the trot, asymmetric vertical head nodding is probably the most obvious sign of weight-bearing asymmetry between forelimbs. Correspondingly, the vertical movement of the sacrum shows less lowering and lifting during the stance phase of the lame hindlimb. The tuber coxae shows a biphasic movement during an entire stride cycle, with a slightly smaller amplitude of motion during the stance than during the swing phase of the limb. Lameness amplifies the difference between these two amplitudes in the affected hindlimb: the vertical amplitude is diminished or even absent during the stance phase and enlarged during the swing phase. Maximal MCP hyperextension was shown to be an indirect measure for the vertical ground reaction force and is reduced in the lame limb at midstance proportionally to the degree of lameness. In a group of horses with moderate to severe lameness, MCP hyperextension decreased on average by 10 degrees, which corresponded to a reduction in peak vertical force of 27%. In the contralateral, sound limb, a minimal compensatory increase of MCP hyperextension could be observed. This may be attributed to increased longitudinal braking forces, which extend beyond midstance. In proximal joints, such as the shoulder and tarsal joints, flexion increases in the lame limb, indicating smooth limb loading controlled by extensor muscles.

Figure 73-1. Kinematic gait analysis. A, The different joints of the forelimbs and hindlimbs, as well as of the neck and selected dorsal spinous processes, are marked with light-reflective spheres. B, Multi-camera setup of the Qualisys ProReflex system (Qualisys Medical AB, Gothenburg, Sweden). Cameras are connected in series to a personal computer. C, The three-dimensional reconstruction of the marker trajectories during a trot phase. (Courtesy SDS Equine Motion Research Cooperation, Uppsala-Utrecht-Zurich.)
The mixed lameness is defined as a lameness where pain or pain reactions are obvious during the stance and swing phases. During the stance phase, the previously mentioned typical changes of a weight-bearing lameness can be observed. During the swing phase, flexion of the affected and linked joints is decreased. Both the maximal flexion and the total range of motion are restricted, which may give the impression of a stiff leg.

Compensatory movements of supporting forelimb lameness can be observed at the sacrum or croup, and those of supporting hindlimb lameness, at the head. These movements may mislead the observer during visual gait assessment and suggest a false lameness in a sound limb without structural or functional lesions. In moderate and more accentuated hindlimb lamenesses, a distinct head nod can be observed during the diagonal stance that includes the lame hindlimb, suggesting a lameness in the ipsilateral forelimb. This compensatory head movement is reported to be more distinguishable than the compensations made by the hind quarter as a consequence of forelimb lameness. This transmission may occur ipsilaterally as well as along the diagonal.

**Kinetics of the Lame Horse**

At the walk, in unilateral forelimb as well as hindlimb lamenesses, reduced loading of the lame limb is compensated primarily by the contralateral limb and to a lesser extent by concurrently loaded limbs.

At the trot, four compensatory mechanisms serve to reduce structural stress—that is, peak vertical force on the affected limb:

1. With increasing lameness, horses reduce the total vertical impulse per stride by increasing stride frequency.
2. The diagonal vertical impulse decreases selectively in the lame diagonal, which causes a shortened suspension phase and a faster transition from the lame to the sound diagonal stance.
3. In forelimb lameness, the impulse is shifted within the lame diagonal limbs to the hindlimb and in the sound diagonal to the contralateral forelimb. In hindlimb lameness, the impulse shift occurs predominantly from the affected to the contralateral hindlimb.

**Figure 73-2.** Schematic illustrations representing the top and the cross-sectional lateral views of the instrumented Mustang 2000 treadmill (Kagra AG, Fahrwangen, Switzerland) for use in determination of vertical ground reaction forces of all four limbs simultaneously. Notice the 18 force sensors and the four triangulation units used to determine the hoof coordinates. (From Weishaupt MA, Hogg HP, Wiestner T, et al: Am J Vet Res 2002;63:520.)

**Figure 73-3.** Force symmetry plots. **A,** Distribution of peak vertical ground reaction forces (Fzpeak) in a sound horse. **B,** The same in a horse with moderate left forelimb lameness. In the lame horse (**B**), the absolute differences in Fzpeak are 764 N between forelimbs and 440 N between hindlimbs. This accounts for a 13.5% Fzpeak asymmetry in the forelimbs and a 8.3% compensatory asymmetry in the hindlimbs. Comparing both diagonal stances, load is shifted forward during the right diagonal stance (cr) and backward during the left diagonal stance (cl). a, forelimb asymmetry index; (LF - RF)/0.5(LF + RF), b, hindlimb asymmetry index; (LH - RH)/0.5(LH + RH), c, distribution of Fzpeak within the diagonal limb pair at midstance (percentage carried by the forelimb); cl, during the left diagonal stance, (LF)/(LF + RH); cr, during the right diagonal stance, (RF)/(RF + LH).
The weight-shifting mechanism along the longitudinal axis of the horse corresponds to the changes in body center of mass movement and is compatible with the conclusions drawn from the modeling of compensatory head movements in lame horses. The reduction or even suppression of the downward head acceleration during the lame diagonal stance phase decreases the momentum in the trunk, thus unloading the lame forelimb but increasing the loading of the diagonal hindlimb. During the sound diagonal stance, the distinct vertical head nod, together with the higher horizontal braking forces in the contralateral forelimb, produces a momentum in the trunk, that increases the loading of the contralateral forelimb and decreases that of the ipsilateral hindlimb.

4. The rate of loading and the peak forces are reduced by prolonging the stance duration in the affected as well as in the contralateral limb.

Except in moderate forelimb lameness, where peak vertical forces increase slightly in the diagonal hindlimb, no compensatory increase in peak vertical force can be observed in other limbs (Fig. 73-4). Likewise, in mild and moderate hindlimb lameness, no compensatory increase in peak vertical force can be observed in other limbs.

Applied Inverse Dynamic Analysis
In clinical studies on horses suffering from superficial digital flexor tendinitis, the specific pattern of the limb joint moments, the load distribution between all flexor tendons, and the effects of therapeutic shoeing were evaluated. Heel wedges were not beneficial for the treatment of superficial digital flexor tendinitis, because the effects of the wedges were limited to the distal interphalangeal joint. In another study, tendon load distribution and limb movement adaptations before and after desmotomy of the accessory ligament of the deep digital flexor tendon were evaluated. Analysis of the gait pattern after surgery showed intra-limb compensation for the lost accessory ligament function through the superficial digital flexor tendon and the suspensory ligament. In a study on sound horses and horses suffering from navicular disease, the forces acting on the deep digital flexor tendon and the navicular bone were measured using inverse dynamic analysis. An unexpected increase in load on the distal sesamoid bone during the initial phase of stance was found in lame horses. This load was reduced by about 24% through orthopedic shoeing using 6-degree heel wedges, whereas eggbar shoes did not reduce the maximal load on the distal sesamoid bone. Similarly, various horseshoe types, which are believed to ease breakover, such as natural balance shoes or quarter-dip shoes, do not reduce distal interphalangeal joint moment or the force on the distal sesamoid bone. However, the ratio of heel to toe height, and the angles of the distal phalanx are well correlated to the forces applied to the foot.

Applied Forward Dynamic Analysis
Forward dynamic analysis is opposite to the approach of inverse dynamics and uses given internal forces combined with segmental data to predict external forces and move-
ments. Both total body movement and specific joint loading during various interventions or loading scenarios can be simulated.\textsuperscript{58,59} The accuracy of the model output depends on the complexity of the model and the accuracy of the input data.

Finite element modeling (FEM) is a method adopted from engineering. Modeling a complex object as a composition of numerous single elements with known material properties and interactions allows the calculation of the effect of external forces on internal stress. FEM has been used to simulate bone or hoof loading patterns.\textsuperscript{60-62}

Depending on the degree of conformity between the introduced properties and the real diversity of microscopic structure, the effects of interventions such as various shoeing can be estimated. For example, several variations of nail or clip placement were tested and their influences on strain and displacement of different hoof wall segments were assessed.\textsuperscript{61}

To answer practical relevant questions, future clinically applied locomotor research will have to combine kinematic and kinetic analysis techniques with complementary methods such as saddle pressure measurements (Fig. 73-5) (see Chapter 77). Further efforts should focus on localizing the precise site of lameness and on evaluation of interventions, not only in terms of changes in locomotion pattern but also on the mechanical effects on internal structures such as tendons and joints, using inverse dynamic analysis. Additionally, basic statements used generally among riders, such as "collecting the horse" can be objectively evaluated and statements can be made in regard to their abilities as riders.

Predictive models of mechanical function will aid surgical decision making and drive rehabilitation of gait by providing normative indications and feedback on efficacy of treatment.

**Figure 73-5.** Combined kinematic, kinetic, and saddle pressure analysis in a study assessing the rider's influence on the biomechanics of the horse. (Courtesy SDS Equine Motion Research Cooperation, Uppsala-Utrecht-Zurich.)

### REFERENCES

LAMENESS EXAMINATION

In a lameness examination, diagnostic analgesia is carried out to assist in the determination of the anatomic site of lameness. It is generally used in horses that are obviously lame or that show a positive response to a flexion or other provocation tests. A detailed discussion of diagnostic analgesia can be found in the textbooks dealing mainly with lameness. Perineural anesthesia is preferred over intraarticular anesthesia because it generates less morbidity.

**Mechanism of Action**

Injury is transmitted to the central nervous system by peripheral nerves. There are specific roles for thinly myelinated A-delta and nonmyelinated C-fibers in signaling pain sensation. Local anesthetics block nerve conduction by preventing the increase in membrane permeability to sodium ions. Local anesthetics exert their effect by inhibiting the rapid inward flow of sodium ions, thereby inhibiting depolarization of the membrane. This can be done by the dissociation of local anesthetic, which alters the electrical forces across the membrane. The order and degree of neural blockade correlate with the diameter and type of nerve fiber and the degree of myelination. The first nerve fibers blocked are the B-fibers; the A-delta and C-fibers are next, and the last nerves blocked are A-gamma, A-beta, and A-alpha. For more details on pain management see Chapter 23.

**Choice of Local Anesthetic Agent**

Mepivacaine is the local anesthetic agent of choice for perineural and intrasynovial analgesia. Its duration of action is 2 to 3 hours, and it causes less tissue irritation than other local anesthetics. Once a bottle of local anesthetic is opened, the efficacy of the drug diminishes rapidly, so it should be used within a few days. Generally, 2% solutions (20 mg/mL) of local anesthetic are used. Sensory nerves are the first to be desensitized, followed by sympathetic and eventually motor nerves. As a rule, because of the irritant properties of anesthetic agents, as little should be injected as is necessary to obtain anesthesia. In severely inflamed or abnormal tissues, a higher concentration or amount of local anesthetic is frequently needed to achieve the desired effect. Local anesthetics penetrate membranes less effectively in an acidic area, such as an infected wound. Diffusion of the anesthetic to its intended site of action is diminished in edematous or scarred tissues, and the anesthetic effect is therefore less reliable.

Adrenalin at a low concentration is often added to a local anesthetic when it is used for perineural anesthesia to induce some vasoconstriction. Although it provides a longer duration of analgesia, adrenalin also imparts a more selective analgesia. Thus, adjacent structures including other nerves and ligaments are affected to a lesser degree. However, the disadvantage of adrenalin is that severe swelling may occur 1 day later. Adrenalin may be responsible for the occurrence of skin necrosis and white hair, which are sometimes observed after diagnostic analgesia.

**Perineural Anesthesia**

Long or dirty hair should be trimmed with a no. 40 clipper blade, and all injection sites should be thoroughly cleaned with antiseptic soap and gauze sponges. A combination of 70% alcohol and chlorhexidine is often used for this purpose. Aseptic preparation of the skin is required before injection of synovial spaces. The clinician’s hands must also be clean because they are used to palpate and locate the nerves under the skin immediately prior to injection.

**Synovial Anesthesia**

Anesthesia of synovial spaces requires sterile gloves, needles, and syringes. Generally, the synovial space is injected using an 18-gauge (1.2-mm-diameter) or 20-gauge (0.9-mm-diameter) needle. Large-gauge needles are better for the collection of synovial fluid, but horses tolerate their placement less well than smaller-gauge needles. The needle is inserted alone without the syringe attached. Depending on the temperament of the horse, a twitch may be used for restraint. This is particularly useful when needles are inserted through large muscles masses—for example, over the shoulder, elbow, and hip joints. A twitch also should be used when injecting complex joints such as the stifle. The operator should always use a competent assistant to restrain the horse, so that sudden movements, which may result in damage to the joint cartilage or needle breakage, are prevented. When the needle is to be inserted over a large distance (shoulder or hip joint), the skin over the injection site should be anesthetized using a small amount of...
anesthetic and a small-gauge needle. For certain procedures, a spinal needle is used because it is flexible and less likely to break. After injection of the synovial space, the horse is walked to promote distribution of the anesthetic agent.

**Needle Positioning for Intrasynovial Anesthesia**

For most synovial spaces, the needle is correctly positioned when synovial fluid flows spontaneously out of the back of the needle. Sometimes, the needle must be turned several times until synovial fluid flows out. When this fails, aspiration of synovial fluid may be attempted, although this rarely works because the synovial villi become lodged in the tip of the needle, thereby blocking flow. Injection of air often produces a characteristic bubbling of synovial fluid in the joint, and a larger amount of injected air sometimes results in backflow of foamy synovial fluid. Another indication of correct needle placement is minimal resistance to the injection of local anesthetic. In special cases, the joint can be radiographed after intrasynovial injection of contrast medium (see Chapter 75).

**Animal Restraint**

Whenever possible, horses should not be sedated for diagnostic anesthesia because the risk of injury while working on the hindlimbs is high. A twitch applied to the nose is an excellent restraining method and makes diagnostic anesthesia easier and safer. However, sedation may be necessary in intractable horses. Detomidine (1 mg/kg intravenously) is ideal and can be reversed. Alternatively, acepromazine (5 mg per horse intravenously) may be used. The use of α₂-agonists for sedation is not recommended because the horse may react violently when the needle is inserted. Additionally, these drugs have two other effects that may be confusing during a lameness evaluation: they induce some analgesia and they produce ataxia.

**EVALUATION OF ANESTHESIA**

**Testing**

The clinician must determine whether the diagnostic anesthesia has achieved the desired effect and the nerve in question has been desensitized before re-evaluation of lameness. A pointed instrument, such as a ballpoint pen, can be used to assess the sensitivity of the skin and deeper structures including tendons and ligaments. A convenient device consists of a stick approximately 1 m long, with a blunt nail positioned at one end. The nail can be conveniently placed on the region of temporarily neutralized sensory innervation of the horse to test the efficacy of analgesia without bending down. Lameness can be evaluated only when the nerve has been correctly desensitized.

**Interpretation**

Lameness is re-evaluated after each injection of anesthetic. The horse should be walked and trotted “in hand” on a hard flat surface. Tests (flexion, moving the horse in a tight circle, hyperflexion, extension) that were positive in the initial examination should be repeated. If required, the horse can also be lunged on soft ground (see later). The response to diagnostic anesthesia can be negative, positive with residual lameness, positive, or positive with lameness in the contralateral limb. A positive response with residual lameness may be difficult to interpret. The most difficult interpretation is that of a lameness that gradually improves after each injection. The results of diagnostic anesthesia may be incorrectly assessed, yielding false-positive or false-negative results.

**PRECAUTIONS**

Interpretation of the results of perineural anesthesia in horses treated with analgesics can be difficult. Therefore, diagnostic analgesia should not be performed until the effects of the systemic analgesics have worn off.

**Horses Suspected of Having Incomplete Fractures**

In severely lame horses (e.g., with tendon rupture, bone fracture), the cause can usually be diagnosed without
diagnostic anesthesia, and in these cases, the area is merely radiographed or examined ultrasonographically. In selected cases, diagnostic analgesia may be carried out before or after radiography to confirm a diagnosis. However, incomplete fractures can progress into complete fractures with displacement after diagnostic anesthesia. Therefore, the horse with a suspected fracture should be walked or trotted in a straight line, in hand, for only a few strides to determine the effects of the anesthetic.

With mild to moderate lameness, the question always arises as to whether horses should be lunged after diagnostic anesthesia. In the author’s experience, several displaced fractures have developed in horses that were lunged after perineural anesthesia. Interestingly, the hindlimbs were more often affected than the forelimbs. The bones most commonly affected are the proximal first phalanx and the distal MCIII/MTHIII. Fractures of other bones after lunging are rare. The following general rules should be observed:

- Horses with acute lameness (up to 6 weeks) should not be lunged.
- The horse must be quiet and under the control of the examiner during lunging; otherwise, lunging should be discontinued.
- Trotting the horse in hand in a straight line is always safer than lunging in a circle.

Every diagnostic anesthetic injection proximal to the palmar digital nerve block increases the risk of fracture; therefore, if an incomplete fracture of the proximal phalanx is suspected, blocks should not be continued above this point.

**Bandaging and Stall Rest**

At the end of the diagnostic analgesia procedure, a bandage moistened with disinfectant solution should be applied to the leg for 12 to 24 hours. This is to prevent swelling associated with the injections in the distal limb. The horse should remain in a box stall for 24 hours. Under no circumstances should a horse be turned out after diagnostic analgesia. Horses should be rested for 3 days after intrasynovial analgesia.

**COMPLICATIONS**

Swelling often occurs for a few days in limbs that have had multiple perineural anesthetic injections. In these cases, the limb must be kept under bandages for days.

In fractious horses, the needle may break and remain under the skin. Whenever possible, an attempt should be made to remove the part of the needle buried in the tissues.

Adjacent structures may be damaged; however, the risk of this is low if a correct approach and proper injection technique are applied.

Infection of synovial structures or cellulitis after perineural or intrasynovial anesthesia is very rare, particularly when aseptic technique has been followed. The risk of cartilage damage and joint infection or inflammation is also very low provided that intrasynovial analgesia is performed correctly. Thus, it usually is unnecessary to advise the owner explicitly of these risks (in the author’s opinion). Joint hemorrhage, which occurs frequently, does not appear to have any adverse effects.15

**APPLICATION**

Perineural analgesia must be carried out in a systematic and logical manner. The aim is to be specific and exact, while avoiding an excessive number of nerve blocks. Generally, the procedure is begun distally, and it progresses proximally. The more distal the nerve block, the more specific is the diagnostic anesthesia. Perineural anesthesia is usually applied medially and laterally at the specific location at the same time. In addition to perineural anesthesia, which usually desensitizes a single nerve (medially and laterally), ring blocks are frequently used to block the entire region distal to the anesthetized area.

**Nomenclature**

The names of the various diagnostic nerve blocks vary depending on the literature consulted. Because of this confusion, a simple classification system was chosen for the tables and figures in this chapter. “F” corresponds to forelimb and “H” to hindlimb. Numbers indicate perineural injection of a nerve or nerve pair. When a ring block is used, it is referred to by the number of the nerve anesthetized.

**Perineural Anesthesia in the Forelimb**

In the forelimb, a palmar digital block is carried out, followed by a low palmar block and a high palmar block.12-16 These are followed by an ulnar nerve block and by desensitization of the medial and cutaneous nerves of the antebrachium. Each positive perineural anesthesia can be followed by a more specific anesthesia, such as intrasynovial anesthesia or anesthesia of a specific nerve after the effect of the previous anesthetic has worn off. In some instances, it may be helpful to block only the medial or lateral palmar digital nerve. The detailed information for these nerve blocks is summarized in Table 74-1 and illustrated in Figures 74-1 to 74-3.

**Perineural Anesthesia in the Hindlimb**

Perineural anesthesia in the distal hindlimb is similar to that described for the forelimb.17 However, there are important differences in innervation, such as the dorsal metatarsal nerves, which must be taken into consideration. Safety of the examiner and horse handler is crucial, so in most cases diagnostic anesthesia is started further proximally, provided that a lower limb problem is not suspected. In some instances, where a problem is expected distal to the metatarsophalangeal joint, a nerve block is first performed in the eastern region, and this is followed by a nerve block proximal to the metatarsophalangeal joint. These blocks are followed by a high plantar nerve block, and by fibular and tibial nerve blocks. The detailed information for these nerve blocks is summarized in Table 74-2 and illustrated in Figures 74-4 and 74-5.

Equine surgery depends heavily on various imaging procedures. Imaging plays important roles—first, in diagnosing and localizing a disease process; second, in assessing the surgical intervention; and third, in the follow-up evaluation of a patient. Many imaging techniques are available. In this chapter, the basic principles of image production and interpretation are discussed.

RADIOGRAPHY
Production of X-Rays

Every radiographic examination is based on the fact that x-rays are attenuated when passing through matter. The chemical and physical properties of matter are the decisive factors in the attenuation process. The attenuated x-ray beam can be registered by appropriate imaging systems. X-ray tubes are used for the production of high-velocity electrons. This highly evacuated glass tube contains the positive (anode) and the negative pole (cathode). The cathode produces the electrons by heating a tungsten filament. The electron cloud is accelerated toward the positive pole of the x-ray tube when a very high voltage is applied.
The applied high voltage dictates the velocity of the electrons. The impact of the electrons on the anode generates the desired x-rays (deceleration x-ray beam emittance), but also it produces undesirable interactions that cause high thermal loading of the anode material (Fig. 75-1).

Several techniques are used to remove the heat from the anode. In the stationary x-ray tube, the anode consists of a small plate of tungsten, embedded in a large block of copper. The copper removes the heat from the tungsten target by conduction. In the rotating-anode x-ray tube, the anode consists of a tungsten alloy disk that is rotated by an electric motor during the exposure. The anode disk has a very high heat capacity, and the area exposed to the impinging electrons changes continuously during the exposure, so heat is distributed. Because heat is dissipated only by convection, it is radiated to the adjacent glass envelope and the surrounding cooling oil. In the rotating anode, the focal spot becomes a focal ring, which, depending on exposure time, is irradiated in part or totally. The metallic tube housing containing the cooling oil surrounds the x-ray tube and shields against the x-ray radiation. The cooling oil also is used as an electrical insulator against the high voltage. A small aperture allows passage of the x-ray beam through the glass envelope in which the x-ray beam is attenuated. The x-ray beam contains a variety of different x-ray intensities. The lower intensities are removed from the beam by appropriate filters, because they increase the radiation burden on the patient but do not have enough energy to penetrate the patient.1-3 Today, every x-ray tube has at least a 2-mm-thick aluminum filter. At the tube housing, a light beam diaphragm with special lead diaphragms is attached. The light beam diaphragm limits the x-ray beam and serves as an aiming device, showing with cross-hairs the position of the central beam (center) (Fig. 75-2).

Image Formation and Storage

Film and Screen Combinations

After passage through the patient, the attenuated x-ray beam is registered by a combination of intensifying screens and specially adapted x-ray film. The most popular imaging system is photographic film that is exposed by the x-rays directly or indirectly through the light emission of the intensifying screens. A so-called latent image of the intensity distribution of the x-ray beam is generated in the film. The image becomes visible after development, fixation, and drying of the film. The intensifying screens contain substances (phosphors) that belong chemically to the rare earth group of elements. They convert the x-ray photons much more efficiently than the formerly used calcium tungstate. The intensification of the screens is divided into three groups. The groups are calibrated so that, from one class to the next, the exposure must be either doubled or divided by two. High-intensifying or high-speed screens have the highest emission of fluorescent light and therefore the highest possible amplification, but resolution is limited (greater than 0.3 mm). Resolution is best described as the ability to discern two neighboring structures. Regular screens are the compromise between high intensification and resolution. High-resolution screens have good resolution (0.1 mm), but their sensitivity is quite low.4 In equine radiography, high-resolution screens should be used to demonstrate bony structures. The evaluation of the navicular

Figure 75-2. The light beam indicates with cross-hairs the center of the beam. The light diaphragm limits the x-ray beam to the region of interest. A lead letter is placed on the lateral aspect of the radiograph to identify the limb of interest.
Digital Radiography

The altered x-ray beam after passage through the patient can be captured with specially designed systems. The most commonly used method is the imaging plate, where the storage phosphor consists of europium-activated fluorohalides. Not only does irradiating the imaging plate cause blue fluorescence but also the larger part of the x-ray energy is absorbed by the phosphor, whereby the electrons are lifted to a higher energy level. The exposed imaging plate can store the latent image without loss of details for several hours. In the “reader,” the stored energy of the phosphors is emitted upon irradiation with red laser light. The emitted fluorescence is blue and is seen by a photomultiplier tube, which converts the light intensities into electric signals. An analog-to-digital converter digitizes the signals and stores them in a computer in form of a matrix. (Because the matrix is stored in a computer, this technology is sometimes referred to as computerized radiography.) The final x-ray image is produced when the data of the image matrix are converted to analog brightness signals by the use of a look-up table.

The x-ray picture can be obtained as a hardcopy on special film or displayed on a monitor screen. The stored image data can be displayed in many ways using different look-up tables. Mostly, images are displayed as conventional radiographs, but image frequencies can be altered to better visualize certain structures such as subchondral cystic lesions or fissure lines. Also edge enhancement can be used to delineate linear structures more clearly. The image data can be stored and later reused. The memory necessary to store a common 24×30-cm radiographic picture lies between 6 and 8 MB. This considerable memory requirement often leads to compression of the image data, but compression always means loss of information. The compression ratio dictates the information loss.

Apart from the storage phosphor technique, other systems exist that are able to store and convert the information of the x-ray beam as modified by the patient. Nearly all systems are based on the same principle: A luminescence screen converts the energies of the x-ray photons into visible light. Using one or several charged-coupled devices, the fluorescent image is converted to electrical signals and thereafter digitized and stored in a matrix. Another method functions like a thin film transistor display. Here, the sensitive photo elements are directly coupled to the luminescent screen. These systems are usually called direct digital radiography (DDRx). The display of the final image also takes place on a monitor screen or as a hardcopy on special film. DDRx is too expensive to be used in equine orthopedics.

A third method is used to convert the x-ray beam into a visible image. The signal of the image intensifier tube may be digitized, stored, and converted by a computer in a way similar to that used by the other digital methods. The only shortcoming of this method is the limited resolution capacity of the image intensifier. The use of the image intensifier in equine practice is quite restricted because of the size and construction of the equipment.

Image Quality

Apart from the resolution, as discussed earlier, image contrast plays an important role. Contrast is defined as the difference of neighboring intensities. High contrast means clear-cut and intense changes of brightness, whereas in low-contrast images the transition from one light intensity into the next is less pronounced and more blurred.

The contrast is mainly influenced by the scattered radiation. Scatter radiation is produced in the examined volume of the patient by the Compton process. The amount of scatter radiation can be drastically diminished by reducing the volume irradiated (the exposure field). This is accomplished by collimation of the beam (Fig. 75-3). In addition, scatter grids can be used to remove, in part, the effect of the generated scattered radiation. The grid consists of a large number of lead foil strips separated by x-ray–transparent spaces. The grid allows passage of the primary beam only. The lead foil strips of the grid absorb radiation that is not perpendicular to the screen. For areas producing a large amount of scatter radiation, grids have to be used to obtain optimal contrasts. Remember the following rule of thumb: if the object to be examined is thicker than 10 cm, the use of a grid is indicated. The use of a grid requires higher exposure values, so collimation of the beam should be done at the same time to reduce scatter radiation of the assisting personnel. The grid ratio is defined as the quotient of the height of the lead strips divided by the length of the interspace through which the primary radiation passes. The grid ratios useable in equine radiography range from 8.1 to 10.1, and the suitable number of lines per centimeter should be not less than 30. Parallel grids are easier to use than parallel focused ones. Crisscrossed grids are best for extremely thick body portions such as the pelvis and femoropatellar joint region (Fig. 75-4).

Inconsistency of image quality also may stem from film development. An automatic processor does all development, fixation, and drying steps. This does not mean that manual processing of the radiographic film is inferior, but it is more susceptible to underexposure, overexposure, and other mistakes.

Basic Image Interpretation

Every radiograph contains the information of a three-dimensional object, and this is compressed into a two-dimensional image. Therefore, every x-ray examination should consist of at least two planes that are oriented at right angles to each other. In many situations, these two standard imaging planes are not sufficient to allow correct interpretation, and additional (e.g., oblique) projections of the x-ray beam have to be used. Image interpretation is easiest when the same standard projections are routinely performed for a given region or joint. On the radiograph, the name of the owner; the age, breed, and sex of the horse; the examination date; and name of the hospital, practice, or institution must be clearly identified. Lead marks for right or left limb are placed in the proximal, dorsal or cranial, upper
corner on a lateral radiograph, and in the proximal, lateral
corner in a dorsopalmar, dorsoplantar, or any oblique
radiograph. The first step to radiographic interpretation is to
assess whether image quality is appropriate and whether the
anatomic region of interest is fully depicted on the imaging
study. Once this has been done, the actual reading of the
radiograph can start.6

A radiograph is a reflection of the different absorptions
and attenuations of the x-ray beam in matter. Only five
different radiologic densities can be demonstrated on a
radiograph—those of gas, fat, water or soft tissue, bone, and
metal. Radiographic density or opacity depends on these
physical and chemical properties, as well as on the thickness
of a given object. Fat is helpful in separating muscle bellies

Figure 75-3. A, Caudocranial view of the femorotibial joint without collimation. B, The identical radiographic view with
tight collimation. The amount of scatter radiation produced within the large muscle mass is dramatically reduced, improving
image quality.

Figure 75-4. A, Lateral radiographic projection of the femorotibial joint without a grid. B, The identical projection with a parallel grid. The image
contrast is improved by reduction of scatter radiation.
and tendinous structures from one another. Reading a radiograph means identifying abnormalities in texture, contour, and structure of the five different densities visible on a radiograph. Radiographs are read in a standard way, and whether this is done from left to right or from top to bottom, or in a more anatomic method from joint to joint, is not important. However, using the same routine all the time helps prevent the oversight of some lesions, particularly when the reader finds an obvious abnormality and stops reading the entire film. Then the various abnormalities are summarized to form a radiographic impression or diagnosis.

Radiography is often the first imaging study used to arrive at a diagnosis, and if the reading is equivocal, further imaging studies may be suggested. These may include additional views in different projections and the application of negative or positive contrast agents. With the introduction of ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI), the use of contrast procedures to assess joint cartilage and synovial membrane has gradually diminished. Abnormal communication of a synovial space and the surrounding soft tissue can be analyzed with an arthrogram, fistulogram, tendonogram, or bursogram (Fig. 75-5). Aseptic centesis of a synovial space should be done and the contrast agent instilled slowly. It is important to bring the contrast agent to body temperature, because viscosity is heavily dependent on temperature of the contrast agents. Nonionic contrast media are less irritating than ionic contrast agents, but they are also more expensive. For larger joints, ionic contrast agents are sufficient. Depending on the joint space, 5 to 20 mL of contrast medium is injected. There is a tendency to use too small an amount of contrast medium, but image interpretation is more difficult when a joint is not fully distended. The joint should be flexed and then the same radiographs are repeated. The contrast medium will be absorbed through lymph and venous drainage quite rapidly.

ULTRASONOGRAPHY

Ultrasonography is an established technique in the diagnostic workup of the flexor tendons, the suspensory ligament, and the check ligament (Fig. 75-6). Ultrasonography of other ligaments, joints, bursae, tendon sheaths, and muscles is becoming more routine. The biggest drawback of ultrasonography is operator dependence. Although it represents a cross-sectional imaging technique, the planes are individually set, and multiple artifacts can make interpretation difficult for the inexperienced operator. Nevertheless, ultrasonography has become an integral part of equine surgery because it is noninvasive.

Image Formation

Diagnostic ultrasonography uses high-frequency sound waves between 2 and 12 MHz. The sound waves are produced in a transducer, and a series of ultrasound pulses are transmitted into the patient. The ultrasound waves are propagated but also reflected to form an image by transforming the returning ultrasound energy into electrical energy. The reflected signal, which corresponds to the anatomy of the structure producing the reflecting signal, is converted into an image and projected onto a monitor. The brightness of a dot on the monitor screen correlates to the amplitude of the returning echo. Different shades of gray are assigned to different echo strengths. The propagation speed of an ultrasound wave is determined by the density and stiffness of a given tissue. The propagation speed is highest in solid tissues such as bone, it is lower in fluid-filled structures, and it is lowest in air. It is the interface between tissues that allows the differentiation of one structure from another. Large differences exist between soft tissue and bone,
or soft tissue and air. The various soft tissue densities differ not minimally and, therefore, tendon structures are easier to distinguish from one another when a fluid-filled tendon sheath surrounds the tendon. Ultrasound waves are also attenuated, scattered, reflected, and refracted. The combination of these interactions of ultrasound waves with tissue creates an image.

The resolution of an ultrasonographic image depends on, among other things, the axial and lateral resolution. Axial resolution is the ability to distinguish the dots along the ultrasound path. This is determined by the pulse length, which depends on the frequency of the transducer. The higher the frequency is, the better the axial resolution. However, the price for the higher resolution is a loss of depth in tissue penetration. Therefore, superficial lesions can be scanned with high frequencies, whereas deep-seated structures have to be examined with low frequencies. Lateral resolution is the minimum distance two dots can be from one another and still be distinguished from one another in a plane perpendicular to the sound wave. This is determined by the diameter of the ultrasound beam. The lateral resolution typically decreases with distance from the transducer, since the beam diverges with distance. Lateral resolution is best in the focal zone. Usually, axial resolution is superior to lateral resolution.

For most structures to be scanned in equine surgery, a high-frequency transducer with good resolution can be used. Various types of transducers exist. Linear probes produce good-quality images and the best overview, but they need a large footprint (surface area on the probe). This may be a problem when curvy, irregular surfaces have to be scanned. Fluid-filled stand-off pads may improve tissue contact. Sector scanners have a smaller footprint.

Ultrasound waves are produced by mechanically oscillating or rotating one or more crystals. Phased-array transducers do not excite the crystals mechanically but use an electrical signal to excite them. One crystal after the other is excited in a timely (or phased) fashion. These transducers have the smallest footprint, but they have less penetration than sector scanners. Color and power Doppler sonography are newer techniques that rely on the Doppler shift as the returning signal is reflected off a moving target, typically red blood cells. Power Doppler ultrasonography is promising for the evaluation of vascularity—or example, in the tendon healing process.

Image Interpretation

Before interpreting an ultrasonographic image, the operator should know the various control buttons on the machine. The amplitude of the returning signal is steered by the power control, which delivers a specific amount of energy to the emitted ultrasound waves. Only the returning signals can be amplified by using the gain setting. Preferentially, the echoes returning from the far field are amplified the most, and the returning signals in the near field are not augmented. When all settings are set correctly, image interpretation is made easier and structures (e.g., the flexor tendons) are assessed for their contour, echo texture, and relative echogenicity. The terms to describe a lesion are relative terms, such as hypoechoic, hyperechoic, and isoechoic.

NUCLEAR MEDICINE

Equipment

Scintigraphic examinations of equine patients became possible about 30 years ago. Scintigraphy is an imaging method used to detect inflammation in tissues, which usually represents the source of lameness in the musculoskeletal tissues. This special imaging method detects gamma rays emanating from the patient who has been injected with a radiolabeled compound, and converts them into visible light. This light is recognized by photomultiplier tubes (PMTs) in a gamma camera and converted into electrical signals, which are thereafter amplified. The detector of the gamma camera consists of a large but thin NaI(Tl) crystal and a large number of PMTs. The PMTs are interconnected with each other in a resistance matrix, so the scintillation event can be localized in the crystal. In front of the NaI crystal, a collimator is placed to select the incident gamma radiation according to the direction of the holes. Depending on the construction of the collimator, only radiation with right-angle incidence or obliquely angled gamma rays can pass through. The size and the number of the holes and the thickness of the septa or “walls of the holes” are the determining factors. The collimators have to be adapted to the energy of the gamma isotopes and the desired resolution. Increasing the resolution always causes a lengthening of the acquisition time. Therefore, collimators with larger holes are often used because their better counting rate makes the duration of the examination shorter. The detector head shields the delicate crystal and the electronic circuitry from external radiation and mechanical shocks.

The gamma camera was developed for the human patient, and using the camera to examine the horse poses some problems. Most cameras consist of two separate elements: the detector head and the acquisition unit that consists of the computer storing the acquired data and a display unit. For the equine patient, scintigraphic application requires special positions for the gamma camera, and many mounting solutions have been developed and used. The best ones seem to be gimbals mounted on an electrically driven cart, or a hydraulic crane mounted to the ceiling of the examination room. Many clinics use only the gamma camera in the standing animal, which reduces the potential of the nuclear examination method quite drastically. The size of the camera also plays an important role. A large-field gamma scintillation camera may cover a large anatomic region but may be very cumbersome to position correctly. Usually, large-field cameras have rectangular or circular fields of view. The very large circular detector head is difficult to position over extremities. A large part of the examination field is not used. The age of the camera is important, too. Many improvements have been made in the design and construction of the collimators. Modern equipment offers better resolution and higher sensitivity.

Image Production and Quality

Examinations are always influenced by the duration of the acquisition, which is limited by the animal’s motion. Image quality is in turn affected by the number of counts.
available: a higher number of counts produces a better image (Fig. 75-7).

In the standing animal, the examination should be as short as possible, so that motion, which interferes with image quality, can be minimized. On the other hand, it is evident that larger count numbers improves the scintigraphic image. A compromise has to be made between short examination duration and the total count number. The easiest way to reduce movement of the patient is adequate sedation or tranquilizing of the horse. Correct handling of the animal is also very important for avoiding motion. Mathematical motion correction programs do exist, but they can be applied only with dynamic studies, and only minor movement errors can be resolved. Examination of the anesthetized patient in lateral recumbency allows longer examination times, and together with the use of high-resolution collimators, this permits delineation of deep structures with more detail.

The source of the gamma radiation is the metabolized radioactive label, and technetium-99m is used as a source of the gamma radiation. $^{99m}Tc$ has a short half-life of only 6 hours and a suitable gamma ray energy of 140 keV. The radioisotope can be eluted with physiologic saline from a generator system. The mother isotope of $^{99m}Tc$ is molybdenum-99. The eluate contains pertechnetate-99m, which is the oxide of technetium and has the chemical formula $\text{TeO}_4$. $^{99m}Tc$ can be coupled to specific organic or inorganic compounds. For example, $^{99m}Tc$ coupled to phosphates will be concentrated in the skeleton, and bone imaging will become possible. Denaturized albumin tagged with $^{99m}Tc$ will stay in the vascular bed. The complex of $^{99m}Tc$ and sulfur colloid will mark the liver, the bone marrow, and the spleen. The quantity of the marker in a vial used in human nuclear medicine is usually sufficient to allow visualization of the desired organs in the horse. However, the activity of $^{99m}Tc$ for a horse has to be increased at least five times. Approximately 4.5 to 7.5 GBq of $^{99m}Tc$ is commonly used for an adult horse. Labeling agents are usually applied by intravenous injection in the jugular vein. In the first phase, the labeling agent circulates in the blood system and can be monitored with a fast dynamic study.

After a few minutes, the label leaves the large vessels and is found mostly in the extracellular fluid and soft tissue. This intermediate stage is called pool phase. After about 2 hours, the target organ (e.g., bone) becomes clearly visible via the uptake of the radioactively tagged imaging agent. The soft tissue activity interferes with the bone activity and decreases image detail. However, soft tissue activity decreases more rapidly than the bone activity, which is primarily the result of decay of the radio-isotope. A large proportion of the imaging label is excreted by the kidneys. This activity will accumulate in the bladder. Therefore, it is useful to empty

![Figure 75-7. Bone scan of the left phalangeal region with 200,000 counts. A, Anatomic detail is poor because of the low count rate. B, Bone scan of the same region with 600,000 accumulated counts, which improved the image quality. A normal uptake pattern is present.](image-url)
the bladder by catheterization if the pelvic region has to be examined.

**Examination Procedure**

The horse receives the radioactive substance by intravenous injection. A catheter is recommended because deposits of the marker behind or around the jugular vein lead to low-count images of the regions of interest. Also, examination of the cervical region becomes difficult or impossible when para-venous deposits of radioactivity are present.

In moderate and cold climates, bandaging of the legs to be investigated at least 12 hours prior to the examination improves uptake of the radioactive agent. The mechanism involved is not clearly understood. At the authors' institution, felt pads are wrapped around the legs. If the hoof region has to be examined, bandages are also applied there. The shoes are removed to access the solar region, too.

For the pool phase, hoof images are acquired after 2 minutes. The contralateral side should be investigated for comparison. After 2 hours, the late or metabolic phase images can be registered. Usually, in the standing, tranquilized animal, only the lateral views of the phalanges and the proximal extremities can be attained without difficulty. In the anesthetized horse, dorsopalmar and palmarodorsal views of the limbs are possible. With a low-energy ultra-high-sensitivity or high-sensitivity collimator, 300,000 (300 k) to 400,000 (400 k) counts can be registered in the lower phalanges. Over large joints, 500 k and greater are easily collectable in most cases. In the pelvic and back region, the limit lies around 1,000 k. For the visualization of the spine, a general-purpose collimator should be used to visualize the spinous processes. In the cervical region, less than 500 k can be gathered without movement of the standing patient even with the high-sensitivity collimator. The amount of collected counts is more important for a correct evaluation than a preset collection time with variable count numbers.

**Image Analysis**

The distribution of the radioactive label in the patient's body can be observed in different ways. The count sampling technique is based on the acquisition of a certain number of counts (preset counts—the preferred method) or limiting the observation period by time (preset time). This procedure is referred to as a static planar study.

It is also possible to register a number of static images with predefined time intervals (e.g., one frame per second, one frame every third second, and so on). The single images are usually called frames. The set of static images is designed as a dynamic study. The data are stored in a dedicated computer that is capable of displaying the results in a dynamic fashion and that allows image manipulation.

With any of these methods, the radioactive data are stored on the hard disk of a computer with dedicated nuclear medicine software. The data are gathered in a matrix representing the field of view of the detector. The matrix sizes for nuclear medicine purposes lie between 64×64 and 256×256. Finer matrices are of no practical value, because the intrinsic resolution of nearly all gamma cameras is larger than 3 or 4 mm. Under practical conditions, the resolution of deeper structures is about 10 mm. So the 128×128 matrix is optimal in most cases. Earlier gamma cameras had only limited memory and hard disk space, so the number of counts storable in a matrix element was also limited. This restriction does not exist in more modern equipment.

The image manipulation programs of modern nuclear medicine software allow filtering of image data, definition of thresholds with upper and lower limits, demonstration of activity profiles whereby the width of the slice can be chosen, and definition of regions of interest (ROI). In the ROI, the number of pixels, the average counts, and the lowest and highest count numbers are displayed. The ROI technique is very useful, allowing calculation of uptake ratios that allow a reference area of interest to be compared with other ROIs. The quotient of the ROI in question and the reference ROI is known as the uptake ratio. The display of the activity distribution on the monitor can be freely chosen to be black and white, white and black, or different color scales. In the authors' experience, the best recognition of anatomic details and structures is achieved with a black and white or the inverted black and white display.

**COMPUTED TOMOGRAPHY**

CT is a radiologic examination method that delivers information in the form of cross-sectional or transverse images. Unlike in conventional radiography, where the image is the sum of all structures penetrated by the primary x-ray beam, CT demonstrates the object free of superimposition by neighboring structures. First, a topogram is made, which produces an overview of the body portion to be scanned, and the position of the patient can be checked and changed if necessary. Then tomograms, which are transverse sections through the topogram, are recorded. After the acquisition of the first transverse section, the patient is moved a small distance and the scanning begins again. This procedure is repeated until the previously defined anatomic field in the topogram is completely examined. CT for horses requires a table that can hold much more weight than commercially available tables. Also, moving the horse and the special table at a constant speed into the gantry is not an easy task. Therefore, a topogram is not usually obtained for horses, and only tomograms are acquired. Instead of moving the table, the gantry can be moved over a fixed table (Fig. 75-8).

The introduction of CT in the early 1970s was a revolutionary step. In the first CT models, the x-ray tube rotated around the patient, emitting a pencil-thin x-ray beam at predefined positions. The tube was coupled to a detector system that registered the altered primary beam. Based on the attenuated primary beam, the attenuation coefficient was calculated according to a simple object model. So, for every direction of the primary beam, a special relationship could be derived, and for the whole series, a set of linear equations for calculating the attenuation coefficients was generated. Further development of CT resulted in larger, fanlike x-ray beams and larger detector elements. The calculation of the attenuation coefficients was no longer done by iterative methods but by convolution and back-projection techniques. In the first 10 years, new generations of CT models were developed in quick succession. An important step forward was the introduction of the spiral CT at the end of the 1980s. With this procedure, the patient is continually scanned, and the x-ray tube and the axial translation are
coupled. In multislice CTs (MSCT), up to 64 different cross-sections can be acquired during one rotation of the x-ray tube. The rotation time of the x-ray tube is only 0.5 second. With this technique and breath holding by the patient, even dynamic processes, such as the beating heart, can be observed. In veterinary medicine, such sophisticated CTs are rare exceptions. However, single-slice CT (SSCT) is used in many clinics and private practices. In SSCT, a single slice is scanned, followed by translation of the patient, and this step is repeated until the object is completely examined as just described. SSCT is less expensive, but examination times are much longer than with a MSCT. Resolution is also less than with MSCT, but by using overlapping slices, 1-mm-thick sections are possible.

The major advantages of CT over routine radiography are the acquisition of transverse or cross-sectional images and superior low-contrast differences. This latter advantage allows the delineation of different soft tissue structures. The acquired density datasets permit reconstruction of the object in a longitudinal or an oblique direction. Three-dimensional reconstruction is also possible (Fig. 75-9). The registered datasets can be stored on a variety of different storage media (MO, DVD, CD, hard disk).

The CT examination can be enhanced with special contrast agents that allow increased soft tissue differentiation and demonstration of tissue perfusion.

CT examinations of animals differ from human examinations in one aspect: animals are examined under general anesthesia. In horses, the examinations are limited to the extremities, neck, and head by the dimensions of the gantry. CT is particularly useful in the evaluation of the equine head, where the cross-sectional images provide much more information than multiple radiographic projections. Occult tooth abnormalities, skull fractures, and ethmoidal hematomas are common indications for CT of the equine head. Because of the anesthesia required, CT is not routinely

![Image](image-url)
used to evaluate complex problems of the limb. However, it gives very good information about bony abnormalities and about soft tissue structures of the phalanges, carpus, and tarsus. Once multislice CT scanners become more common, shorter anesthesia time may allow CT of the lower limb to become more routine.

MAGNETIC RESONANCE IMAGING

MRI generates cross-sectional images of the patient using the nuclear spins of certain atoms. This modality does not use ionizing radiation. Any moving electrical charge is an electrical current and generates a magnetic field. Atomic nuclei with uneven proton and neutron numbers have a rotational motion (nuclear spin) like that of a spinning top. The nuclear spin consists of the single-spin elements of the nuclear components such as the neutrons and protons. The spin of the nucleus produces a magnetic moment. The simplest nucleus is the hydrogen nucleus with one proton. Hydrogen is very abundant in biologic material.

Under normal conditions, the spins of the hydrogen nuclei are randomly distributed and the mean magnetic moment is zero. In a strong magnetic field, the orientation of the spins becomes either parallel or antiparallel to the magnetic field lines. The orientation of the spins in the parallel field direction is slightly larger than in the antiparallel one. Therefore, a measurable magnetic moment exists. This surplus causes an observable magnetic moment. It can easily be influenced by an additional magnetic field such as the one generated by radiofrequency (RF) coils. The MRI machine generates a radiofrequency pulse that is specific to hydrogen. The protons absorb the energy of the pulse, and this causes them to spin or precess in a direction different from that of the original magnetic field. The specific frequency, called the Larmour frequency, depends on the strength of the main magnetic field and the tissue under examination. When the RF pulse is turned off, the protons of the hydrogen slowly return to the original alignment within the magnetic field. When this happens, they release the stored energy. The released energy is picked up by the RF coil as an electric signal and transmitted to the computer system. The coils are designed in such a way that they closely fit the body contours of the patient. Many different RF coils are available for the different body parts. At approximately the same time that the RF coil is activated, the three gradient magnets jump into action. They are arranged in such a way inside the main magnet that when they are switched on and off very rapidly, they change the main magnetic field locally in a specific manner. This means that a desired area in the patient can be selected and imaged. The slices in MRI are very precise and a few millimeters thick. The orientation of the slices in the patient can be chosen freely. This is a huge advantage over all other imaging modalities.

The relaxation times describe the return of proton spin into the equilibrium situation in the main magnetic field. The relaxation is influenced by spin-lattice interactions and the neighboring atomic structures. Spin-lattice relaxation
produces thermal equilibrium, reflecting the parallel or anti-parallel orientation of the protons. The spin-lattice relaxation time is also called T1. The influence of the precessing protons on each other depends on the fluctuating intermolecular magnetic fields. The parallel orientation among the protons subsides with a time constant T2. T2 is usually much shorter than T1. With T1 and T2 image modalities, tissue properties can be characterized, so they are used to differentiate between tissue and tumor. As with all other imaging modalities, the signal-to-noise ratio limits the resolution. Therefore, the volumes of voxel chosen have to be large enough to get a reasonable signal-to-noise ratio using acceptable imaging times. As in classical radiology, contrast agents can be used to improve the contrast behavior of certain tissues. Usually paramagnetic substances containing metallo complexes are used. MRI contrast works by altering the local magnetic field in the tissue under examination. Normal and abnormal tissues respond differently to this slight alteration, giving different magnetic signals. These altered signals are transferred to the images, which allows visualization of various types of tissue abnormalities and disease processes.

MRI is the ideal imaging modality for soft tissues. Tumors in the brain and infections of the brain, spine, and joints are much better demonstrated by MRI than by any other method. Ligaments and tendons can be investigated in detail. Torn ligaments and damaged tendon tissue can be localized exactly and the extent of the lesion visualized.

The major shortcoming of MRI for the equine patient is the necessity of general anesthesia to use its full potential. Small stationary MRI units have been developed for the examination of the lower equine limb, but the limiting factor is patient movement. Additional information of MRI physics and clinical examples of MR images are found in Chapter 76.

**CLINICAL APPLICATION OF DIAGNOSTIC MEDICAL IMAGING**

**Distal Interphalangeal Joint**

The distal interphalangeal joint is radiographed with the horse’s hoof placed on a wooden block. Routinely, a horizontal lateral view and an angled dorsopalmar or dorsoplantar view is obtained first. Oblique projections at 45-degree angles from dorsomedial and dorsolateral, respectively, may be added. Rarely, a horizontal dorsopalmar or dorsoplantar view is obtained. This projection allows visualization of the joint space but is also the only projection in which the thickness of the medial and lateral hoof wall can be measured. This is sometimes helpful for the farrier when hoof balance is in question. A dorsopalmar or dorsoplantar view at a 60-degree angle to the floor with the horse’s hoof placed forward is routinely taken to assess the distal phalanx. Additional, oblique 45-degree views are taken when a fracture of the distal phalanx is suspected.

It is advisable to obtain four views, a dorsopalmar or dorsoplantar, a lateral, and two oblique views, when a nondisplaced fracture is suspected. The distal interphalangeal joint may be altered by osteoarthritis, typically seen as new bone formation at the extensor process, the medial and lateral aspects of the articular surfaces, and the articular margins of the distal sesamoid (navicular) bone. The joint space may become incongruent. Rarely, subchondral bone sclerosis can be visualized. Cystlike lesions may be present in the subchondral bone of the distal or the middle phalanx.

A variety of different types of fractures of the distal phalanx can be diagnosed (Fig. 75-10). The solar border of the distal phalanx may become very irregular and lucent with pedal osteitis. On scintigrams, an increased uptake is seen in the pool phase, most accentuated in the dorsal aspect of the normal distal phalanx. This occurs because of the naturally occurring hyperthermia of this region. The dorsal hoof wall is evaluated in laminitis. The dorsal contour of the hoof wall and the distal phalanx in the lateral projection is no longer parallel when a rotation of the distal phalanx has occurred. Pododermatitis causes focal increased accumulation of the bone label in the toe region. Most often, the pool phase shows localized hyperperfusion. Extremely high concentrations in the toe region are seen in laminitis. The highest accumulation of the bone tracer is seen with fractures of the distal phalanx.

**Distal Sesamoid Bone**

The distal sesamoid bone requires the best possible image quality to identify subtle lesions. High-resolution screens, collimation, and good positioning techniques help achieve this goal. For the evaluation of navicular disease, both distal sesamoid bones are routinely radiographed. A lateral radiograph is obtained with the horse’s hoof placed on a wooden block. The central beam is directed in an imaginary line representing the continuation of the deep digital flexor, approximately 2 cm below the coronary band. It is very important that the central beam hit the cassette parallel to the bulbs of the heels. Otherwise, the distal sesamoid bone is projected obliquely, and this makes interpretation more difficult. The second view is taken with the hoof placed on a specially constructed wooden block. The angle of the block to the floor is 55 degrees. The central beam is directed horizontally or 5 degrees downward in the midline, approximately 1 cm above the coronary band. To avoid artifacts,
the collateral sulci of the frog are filled with a tissue-equivalent material (playdough). The third projection, the tangential view, is performed with the horse’s hoof placed under its belly. This limb is not bearing weight, and the x-ray tube is positioned under the horse’s belly. The tube-to-cassette distance therefore is usually less than 1 m, but this depends on the size of the horse. Approximately the same distance should be used for both forelimbs. This palmaroproximal–dorsodistal view is performed with an angle of 45 degrees to the floor (Fig. 75-11). With a very steep pastern, this angle is increased to 55 degrees; horses with a sloping metacarpophalangeal or metatarsophalangeal angle require a flattening of the angle to 35 degrees to avoid superimposition of the palmar or plantar aspect of the metacarpophalangeal or metatarsophalangeal joint. The beam is centered over the deepest point between the bulbs of the heel. There is a tendency to center the beam too far palmar or plantar. To avoid backscatter from the hoof and the floor, tight collimation is used.7

The lateral view gives information not only about the navicular beam itself but also about the limb axis and particularly about the distal interphalangeal joint and the distal phalanx. The articular surface of the distal sesamoid bone should be smooth; the spongiosa should be regular and fine and clearly delineated from the subchondral bone of the flexor surface. The flexor surface itself is smooth. On a perpendicular view, the sagittal ridge of the distal sesamoid bone is visible. Sometimes, there is a small indentation in the sagittal ridge slightly distal to the middle portion. This is a normal variation and should not be misinterpreted as an abnormality. The dorsopalmar or dorso-plantar view depicts the distal sesamoid bone superimposed on the middle phalanx. This should be noted because (1) lesions in the middle phalanx may be falsely attributed to changes in the distal sesamoid bone, and (2) smaller lesions in the distal sesamoid bone may not become apparent. The distal sesamoid bone normally has a regular bony pattern. The proximal and distal borders should be smooth. Typically, two contours are recognizable, one for the articular surface and the other for the flexor surface. The tangential or skyline view is the best to depict subtle or early changes. The distal sesamoid bone is superimposed only over the palmar processes, and the center region, where most pathology is seen, is free of superimposition. Again, artifacts may occur because of the frog. The distal sesamoid bone normally has a smooth flexor surface, with a more or less pointed sagittal ridge. The subchondral bone of this flexor surface should have the same thickness from medial to lateral. There may be a crescent-shaped small lucency in the area of the sagittal ridge, which represents the indentation described earlier.

The most common reason to radiograph the distal sesamoid bones is suspected navicular disease (Figs. 75-12 and 75-13). This term includes a variety of radiographic findings. The most typical radiographic pattern found in navicular disease is a defect or lucency in the subchondral bone in the sagittal ridge region (Fig. 75-14). In these cases, the spongiosa in this region is sclerotic, and the junction between the spongiosa and the subchondral bone plate becomes indistinct. This may or may not be accompanied by distention of the channels at the distal (and less frequently at the proximal) border of the distal sesamoid bone. The so-called channels represent synovial invaginations of the distal interphalangeal joint. Spurring at the lateral (and less frequently at the medial) proximal distal sesamoid bone border may be present. Sometimes, small fragments at the distal aspect of the distal sesamoid bone, usually medially.

![Figure 75-11](image1.png) Normal radiographic appearance of the distal sesamoid bone in the tangential projection taken at a 45-degree angle relative to the floor.

![Figure 75-12](image2.png) Lateral radiographic view of a distal sesamoid bone with marked sclerosis of the spongiosa in the proximal region of the bone. No delineation between the flexor cortex and the spongiosa is visible.

![Figure 75-13](image3.png) Lateral radiograph of a distal sesamoid bone with a cyst within the spongiosa. This is a very rare finding and is attributed to the osteochondrosis complex.
and laterally to the sagittal ridge, may be present. They most likely stem from separate centers of ossification. True avulsion fractures of the distal or proximal edge of the distal sesamoid bone are rare and typically cause lameness. Sagittal or parasagittal fractures of the distal sesamoid bone are rare. Rarely, bipartite distal sesamoid bones may pose a problem in the diagnosis of a fracture. Small spikes on the flexor surface can be seen with high-quality radiographs. Such spikes most likely represent calcifications and are probably secondary to navicular bursitis. With septic navicular bursitis, the flexor cortex appears lucent approximately 7 days after the insult (e.g., a penetrating wound). The navicular bursa can be imaged ultrasonographically, but the procedure is demanding and requires softening of the solar region of the hoof.

MRI and CT are very good tools for the evaluation of the distal sesamoid bone. MRI in the standing sedated horse produces adequate images, but it is susceptible to artifacts, mostly because of motion. Scintigraphic scanning of the distal sesamoid bone is carried out with the horse's hoof placed on the scanning head and from the lateral aspect with the horse positioned on a block of wood (Fig. 75-15). Very intense uptake in the distal sesamoid bone is usually associated with radiographic changes compatible with navicular disease. However, in some cases, this imaging pattern is the only obvious finding. When the image is not well demarcated, inflammation of the distal sesamoid bone is usually the cause. This is quite often observed together with accumulation of the bone label in the deep digital flexor tendon. Prognosis appears to be more favorable with this finding than when the uptake is more intense.

The insertion of the deep digital flexor tendon can be the site of high uptake, suggesting tearing. By combining the pool and late phase images, the lesion can be further evaluated. Increased perfusion is seen with soft tissue involvement and hyperemia. Lack of hyperemia in the early imaging phase can be interpreted as only bony involvement. The enhanced accumulation at the insertion site seems to have a fair prognosis. Radiographically, often no abnormalities are found with this condition.

The lateral scintigraphic view quite often allows better localization of the exact site of increased uptake. Uptake at the insertion of the deep digital flexor tendon (DDFT) can easily be distinguished from other pedal bone disorders. Uptake in the distal sesamoid bone region is not always easily distinguished from active ossification of the cartilage of the pedal bones. The solar view or the dorsal view helps in such situations.

Sometimes the ossified cartilages of the pedal bones are fractured. In the bone scan, a line of intense uptake is seen.

**Proximal Interphalangeal Joint**

The radiographic technique for the proximal interphalangeal joint is less demanding than for the metacarpopha langeal or metatarsophalangeal joint. Again, lateral and dorsopalmar, dorsoplantar radiographs are obtained, as well as two oblique views at 45 degrees. The angle of the dorsopalmar view is less than that for the distal interphalangeal joint, approximately 10 degrees, because the angulation of the joint is less. The most common finding of this joint is osteoarthritis. Large osteophytes, enthesiophytes, and periosteal proliferations (ringbone) at the dorsal aspect of the proximal and middle phalanx, and various degrees of joint incongruity are common. Subchondral bone cysts may be found, both in the distal epiphysis of the proximal phalanx and in the proximal aspect of the middle phalanx. Fractures do occur in the middle phalanx but seem to be less frequent than in the proximal phalanx.

Scintigraphy is less rewarding in the middle phalanx. Cystlike lesions can cause increased uptake, but quite often only normal or reduced bone metabolism can be detected. Periarticular new bone formation around the proximal interphalangeal joint shows little bone activity. Sometimes the insertion of the superficial digital flexor tendon is associated with increased uptake as a result of tearing. Osteoarthritis of the proximal interphalangeal joint is easily recognized by a clearly delineated enhanced uptake. The tendon sheath, the flexor tendons, and the distal sesamoidean ligaments are best imaged with ultrasonography. CT and MRI have been described but are not routinely performed.

**Metacarpophalangeal and Metatarsophalangeal Joints**

The metacarpophalangeal and metatarsophalangeal joints are two of the most commonly radiographed regions of the horse. The radiographic technique appears to be simple;
however, it is quite difficult to obtain properly positioned radiographs. This can be explained by the lack of clear anatomic landmarks that can be used for positioning the limb and centering the x-ray beam. The minimal standard investigation consists of two imaging planes at right angles to each other. A good lateral view should show the articulation without any distortion, and the articular radius of the metacarpal condyle with the proximal phalanx is smaller than the radius for the condylar articular surface near the sesamoid bones. The dorsopalmar projection should be taken in the direction of the sagittal plane of the forelimb. The central beam is directed approximately 20 degrees from proximal to distal to avoid superimposition of the distal border of the joint with the sesamoid bones. A dorsopalmar radiograph is orthogonal to the joint when an imaginary line between the sesamoid bones falls into the sagittal groove of the proximal phalanx (Fig. 75-16). If this is not the case, the medial and lateral aspects of the articular surfaces become more pointed, and this is often misread as osteophytosis.

Two additional oblique views should be obtained to assess not only the sesamoid bones but also the articular margins of the joint. The dorsal aspect of the sagittal ridge of MCIII/MTIII can best be demonstrated by a lateral

![Figure 75-16. Dorsopalmar (A), lateromedial (B), and flexed lateral (C) radiographs of a normal metacarpophalangeal joint. Note the correct positioning enabling easier image interpretation.](image-url)
projection with the joint flexed. A number of additional oblique projections with proximodistally tilted x-ray beams allows identification of unusual disorders of the proximal sesamoids and plantar fractures of the proximal phalanx (Fig. 75-17). A special dorsopalmar projection with the limb positioned on a farrier’s stand enables inspection of the caudal joint space, mostly to detect condylar fractures. Sometimes, multiple oblique views are necessary to completely characterize fractures of the proximal phalanx before surgical intervention.

For the evaluation of the metacarpophalangeal or metatarsophalangeal joint, the following radiographic criteria should be checked: soft tissue shadows, articular space, joint margins, subchondral bone density, articular surface continuity, marginal osteophytes, intracapsular and intra-articular new bone formation (enthesiophytes), and the presence of osteochondral fragments.

Subchondral sclerosis, osteophytes, and enthesiophytes (usually at the dorsal articular surface) are quite common findings. The high frequency of these signs makes the evaluation of their clinical significance quite difficult. If clinical signs are localized to this joint, these radiographic signs are more likely the result of osteoarthritis.16

Intra-articular fragments are found quite frequently, especially in the younger horse. The frequency of bony fragments in the dorsal part of the joint is higher. In a recent study, the authors found that the presence of bone fragments in the dorsal joint space was twice as likely than in the palmar or plantar space.17 Some fragments represent avulsion fractures, and their origin may show a fracture bed. Free fragments in the dorsal joint space are more likely to represent osteochondritis dissecans, and quite often the dorsal sagittal ridge of the third metacarpus or third metatarsus has an irregular bony contour representing the fragment bed. For most of the other osteochondral fragments, no fracture bed can be demonstrated with radiographs.

Circumscribed radiolucent areas in the subchondral bone may represent cystlike lesions (Fig. 75-18). They can be observed in the bone plate of the mid-sagittal groove of the proximal phalanx or in the condyles of the third metacarpus or third metatarsus. Fine radiolucent discontinuities originating from the dorsal part of the sagittal groove of the proximal phalanx in horses with moderate or severe lameness represent fissure fractures.18 For the evaluation of the proximal sesamoid bones, the borders and the bone structure are assessed. Irregular bone margins and radiolucent areas are signs of recent bone trauma. Avulsions of bony fragments occur at the apex as well as at the base of the proximal sesamoid bones. The fracture bed is usually easily located. Enthesiophytes of the distal and proximal articular surface of the sesamoid bones is associated with osteoarthritis.

Ultrasonography is commonly performed in the metacarpophalangeal or metatarsophalangeal region. Certainly, the flexor tendons, the short and long distal sesamoidean ligaments, the annular ligament, and the dorsal aspect of the joint, including the bony surfaces of the metacarpal or metatarsal condyle and the proximal phalanx, can be visualized. A detailed description of ultrasonographic changes of the flexor tendons is presented in Chapter 86.

Figure 75-17. An oblique projection angled 45 degrees from proximal to distal to visualize the plantar aspect of the metatarsophalangeal joint. Note the small fragment located at the plantar articular rim.

Figure 75-18. Oblique dorsopalmar view of a metacarpophalangeal joint. There is a focal lucency, surrounded by sclerosis at the medial proximal aspect of the proximal phalanx. Diagnosis: cystlike lesion.
On scintigraphy, the metacarpophalangeal or metatarsophalangeal joint very often shows quite intriguing findings, e.g., increased uptake in the dorsal aspect of the joint, linear or multifocal uptake along the joint surface, and uptake in the proximal sesamoid bones. The proximal phalanx may also show abnormal uptake at the insertions of the ligaments. Not all of these signs have clinical significance or show radiologic alterations, and only a thorough lameness examination may prove their clinical relevance. Typically, the metacarpophalangeal or metatarsophalangeal region is examined scintigraphically with a lateral approach. Dorsal views can be easily achieved by holding the front hoof on a farrier’s stand and positioning the camera dorsally onto the limb. This view allows the detection of abnormal uptake in the subchondral bone plate and in the sagittal groove of the proximal phalanx. The evaluation of the distribution of the bone label in the proximal sesamoid bones is not so simple with this view, because of superimposed articular structures. The true distribution of the bone label of the proximal sesamoid bones is therefore best performed with palmar views, which are rarely possible in the standing animal. Findings detected in the proximal sesamoid bones include increased or reduced uptake in the apex, at the base, or near the articular surface.

**Metacarpus and Metatarsus**

A special location to evaluate in the metacarpal or metatarsal region is the origin of the suspensory ligament (the interosseus muscle) at the palmar or plantar aspect of the MCIII or MTIII, respectively. Radiographically, an avulsion fragment may be present in the acute phase; more chronically, the bone pattern in the plantar or palmar aspect of the MTHI/MCIII is irregular and sclerosed. Ultrasonography may (or may not) depict any lesion on the proximal suspensory ligament. Acute lesions have hyperechoic regions of various sizes; more chronic injuries are recognized by an altered fiber pattern, increased diameter of the ligament, and calcification. CT depicts these changes even more clearly; however, the need for general anesthesia often precludes the use of CT.

Scintigraphy is used to detect metabolic bone changes in this region. Trauma produces intense focal accumulation of the bone label. Uptake ratios can be calculated to compare ROI of the origin with an adjacent ROI of the cannon bone or with soft tissue. High ratios (bone, 4:1; soft tissue, 12:1) signify a fresh lesion. The metacarpus is assessed with a lateral and a dorsal view. The most frequent abnormalities are linear, focal, or multifocal concentrations of the labeling agent in or along the splint bones. The clinical significance of such signs is usually quite low. MCII/MTIII show one or two linear regions of higher uptake representing the dorsal and caudal cortices. Stress fractures show intense linear uptake in an oblique direction. It is not uncommon to see intense focal spots in the medullary cavity of MCIII/MTIII. This behavior is known as enostosis. Their significance is controversial.

**Carpus**

The carpus is a very complex anatomic structure, so it is necessary to use multiple beam angles for radiographic evaluation. The simplest views are the dorsopalmar and the lateromedial projections. However, these views often demonstrate lesions of the small cuboidal bones in the proximal and distal row. Two oblique views, one at an angle of approximately 30 degrees from dorsomedial and the other 45 degrees from dorsolateral, are used to depict the dorsal contour and to visualize the accessory carpal bone and the vestigial metacarpal bones. Special skyline views are added when the third carpal bone or the radial and intermediate carpal bones have to be assessed. The flexed lateromedial projection allows the best visualization of the deeper aspects of the middle carpal and the antebrachio-carpal joints. This view is also very helpful in separating lesions of the small cuboidal bones, which are superimposed on the straight lateral view. Therefore, if a practitioner has only two radiographic cassettes, the dorsopalmar, lateromedial oblique and flexed lateromedial views should be taken to get the most information on carpal pathology.

Several anatomic variations should not be read as pathologic findings. For example, the remnant of the styloid is the first carpal bone, which is present in approximately 40% of all horses. An irregular, almost cystlike pattern in the accessory carpal bone is also normal. The radiographic changes seen in the carpus depend heavily on the use of the horse. Racehorses commonly suffer from various forms and degrees of carpal disorders, including slab fractures and sclerosis of the third carpal bone, as well as osteochondral fractures of the distal aspect of the radial and intermediate carpal bone. The other small cuboidal bones are less frequently affected. Hyperextension injuries and repeated trauma to the carpus result in periostal and articular reactions, mostly at the dorsal surface of the carpal bones. This is accompanied by dorsal soft tissue swelling, which often includes joint effusion. Fractures of the accessory carpal bone may occur both in racehorses and in jumping or event horses. The fracture may be articular or nonarticular. Horses not used for racing are far less commonly affected with carpal injuries. Osteoarthritis is sometimes seen in the antebrachio-carpal joint and will be recognized by enthesiophytosis of the lateral and mostly medial aspects of the distal radius and radial and ulnar carpal bones, respectively. The subchondral bone density increases, and the joint space becomes irregular. Osteochondrosis lesions are rare in the carpal region, but when present, they usually appear as subchondral cystic lesions in the distal radial epiphysis.

Ultrasonography is a good technique for evaluating the tendons at the dorsal carpal area and the carpal sheath. Typically, radiography is performed first, followed by ultrasonography to distinguish articular distention from tendon sheath abnormalities. In addition, the integrity of the individual tendons and collateral ligaments can be analyzed.

Although ultrasonography is usually the modality of choice because it can be performed in the standing horse, it lacks the topographic overview, and CT and MRI are superior and easier to interpret. Both bony and soft tissue structures can be assessed at the same time. Limitations are cost and the need for anesthesia.

Scintigraphy seems to play a less important role in the carpal region. It is mostly used to detect occult fractures. In the medullary cavity of the distal radius, an increased uptake can be found, which is called enostoses and is similar to
panostitis in dogs. Fissure and stress fractures in the distal radius are easily diagnosed with bone scanning.

**Tarsus and Tibia**

The radiographic examination of the equine tarsus is based on at least two projections at a right angle to each other. Additional oblique views facilitate the radiographic interpretation. The x-ray beam should always be centered over the distal intertarsal joint, because this is the joint most frequently affected. The direction of the x-ray beam of the lateral view is not really at 90 degrees to the median plane but rather at an angle of 105 to 110 degrees. It is important that the limb under examination be weightbearing. For the oblique and dorsoplantar views, this can be achieved by holding up the front leg on the examination side. For the lateral view, two possible positions are used. In the first one, the contralateral side is held up by an assistant and the x-ray beam is oriented parallel to the floor. In the second method, the horse is standing squarely on its rear legs but the projection of the x-ray beam is slightly angled downward (7 degrees). The centered beam is still aimed at the distal intertarsal joint. High-resolution rare-earth intensifying screens are recommended. If images with more detail are desired, a scatter grid is a necessity.

The radiographic examination of the equine tarsus is based on at least two projections at a right angle to each other. Additional oblique views facilitate the radiographic interpretation. The x-ray beam should always be centered over the distal intertarsal joint, because this is the joint most frequently affected. The centered beam is still aimed at the distal intertarsal joint. High-resolution rare-earth intensifying screens are recommended. If images with more detail are desired, a scatter grid is a necessity.

The tarsal regions most likely to have radiographic changes are the distal intermediate ridge of the tibia, the lateral trochlear ridge of the talus (both frequent locations of osteochondrosis [OC] lesions), and the intertarsal articulations. The OC fragments of the distal intermediate ridge of the tibia may appear radiographically separated, but they are frequently held in place by the articular cartilage or soft tissue. Loose fragments are usually situated in the lowest part of the joint cavity, which extends all the way down to the level of the proximal row of tarsal bones. The use of a high-intensity examination light may be helpful to detect poorly mineralized bony fragments. In the talocrural joint, OC may cause degenerative changes. The dorsomedial to plantarolateral view is best for depicting the lateral trochlear ridge and its osteochondritis dissecans fragments. At the distal end of the medial trochlear ridge, one may occasionally find a small, calcified shadow, which does not seem to cause any clinical signs. Cystlike lesions are rare but have been observed at the base of the talus. Compression of the third or central tarsal bone can be found in foals. Slab fractures of the third and central tarsal bones may be diagnosed in racing breeds. Avulsion fractures of the articular borders of the medial or lateral malleolus quite often occur in the jumping and the cutting horse. The exact position of the fragment should be identified with oblique radiographs before surgical removal.

The most common disorder of the tarsus is osteoarthritis of the distal and proximal intertarsal and tarsometatarsal joints. Changes of the distal intertarsal joint are most frequently observed, followed in frequency by changes of the tarsometatarsal and proximal intertarsal joints. The typical radiographic alterations are subchondral sclerosis, marginal osteophyte or enthesiophyte formation, alterations in the width of the articular space, and deformations, especially of the dorsal contours of the third and central tarsal bones. One of the most valuable signs for the evaluation of the diseased tarsal joints is narrowing and disappearance of the synovial groove. This sign is very reliable, but is easily seen and inspected only in radiographs of excellent quality and positioning. In general, only the synovial grooves of the distal intertarsal and the tarsometatarsal articulations are clearly demonstrated. The groove of the proximal intertarsal joint is usually not sufficiently depicted. In osteoarthritis, the synovial groove becomes unapparent because of newly formed bone.

In the assessment of tarsal radiographs, the talocalcaneal articulation and the sustentaculum tali should not be overlooked. The talocalcaneal joint is normally seen as a discrete, straight, radiolucent line. The articular space becomes irregular, and subchondral sclerosis and osteolysis are present in the case of osteoarthritis. This finding is clinically relevant. The sustentaculum tali is usually affected in conjunction with inflammation of the tarsal sheath. A special skyline view can be taken to evaluate the surface of the sustentaculum tali. The surface becomes irregular and roughened when the sheath is chronically affected. The radiographs of the tarsus are an important part of the pre-purchase examination, because the clinical examination sometimes seems to be inconspicuous even when marked joint alterations are present.

Whereas radiography is commonly used to find bony changes, ultrasonography adds information on the soft tissues. The plantar ligament, the tarsal sheath, and the calcaneal bursa are the most commonly affected structures. Ultrasonography may be very useful to assess joint fluid and synovial hypertrophy of the tarsocrural joint. Again, CT gives even better anatomic detail.

Scintigraphy is used to detect early osteoarthritis, and trauma and tears at the insertion of collateral ligaments. Focally increased concentrations of the imaging agent may be observed in the joint spaces (distal intertarsal, tarsometatarsal, and occasionally the proximal intertarsal joint), representing well-developed chronic osteoarthritis with no apparent radiographic alterations.

Fatigue or stress fractures of the tibia are very difficult to visualize in the early stage on radiographs. Stress fractures of the tibia produce a distinct uptake pattern.

Focal uptake in the medullary cavity may represent exostosis. In the proximal part of the tibia, very intense and well-delineated regions of high uptake can be caused by avascular areas or bone infarcts. Smaller uptake regions of similar intensity can also be observed in fissures of the tibial plateau.

**Proximal Limb**

The large joints, such as the femoropatellar, femorotibial, coxofemoral, and scapulohumeral joints, are best radiographed under general anesthesia. Although it is possible to examine the most proximal joints in the limbs in a standing sedated horse and accept lower image quality, it is not
advised to radiograph the coxofemoral joint without general anesthesia. The scatter radiation to which assisting personnel will be exposed must be taken very seriously. Protective lead aprons and gloves reduce the radiation only partially. Because large soft tissue masses have to be penetrated by the x-rays, a large amount of scatter radiation is produced, which in turn decreases image contrast. To improve image quality, grids have to be used and tight collimation is mandatory. Cones and other x-ray beam limiters are useful, particularly in the stifle region.

**Cubital Joint and Humerus**

The radiographic examination of the cubital joint is easier than that of the scapulohumeral joint. General anesthesia is not necessary. The mediolateral view is obtained with the leg pulled forward and downward. The craniocaudal view is taken with the leg positioned slightly cranially to allow room for the cassette to be placed caudal to the olecranon. The central beam is angled slightly downward. The most frequent findings in the elbow region are various types of fractures of the olecranon. Subchondral bone cysts may be found in the proximal radius. Primary degenerative disease is rare.

The collateral ligaments are accessible for ultrasonographic scanning and may show alterations in fiber alignment, size, and echogenicity.

Scintigraphy may be helpful in the detection of smaller subchondral bone cysts (Fig. 75-19). The anconeal process can be traumatized, producing a very high tracer uptake. Finally, stress fractures may occur. Their usual site is the distal part of the humerus. In the acute phase, the uptake region is very clearly delineated.

**Scapulohumeral Joint**

Most examiners image the shoulder in the standing tranquilized horse with the affected leg extended cranially. The beam is centered from medial to lateral, with a slight angle from cranial to avoid superimposition of the contralateral shoulder region. Oblique and skyline views can be taken to outline the tubercles. The resulting images may be of

![Figure 75-19. Lateral (A) and craniocaudal (B) scintigraphic view of the cubital joint. There is marked focal uptake of the bone tracer in the proximal radius. Mediolateral (C) and craniocaudal (D) radiographs document a large subchondral bone cyst in the proximal radius.](image-url)
satisfactory quality and allow a radiographic diagnosis. If this is not possible, the horse should be anesthetized lying with the side under examination on the imaging system. This allows the use of the scatter grids, small examination fields, and screens with higher resolution. The positions of the standing and of the anesthetized horse are identical; the limb has to be pulled cranially and upward. The central x-ray beam is aimed at a point just below the cervical spine at the base of the thoracic inlet. If everything has been done correctly, the resulting image shows the shoulder joint lying in the shadow of the trachea, free from the rib cage and below the cervical spine. The articular space with the proximal humerus and the distal part of the scapula will be visible. The most common findings include fractures of the supragnoid tubercle, and of the greater, intermediate, or lesser tubercle. Very rarely, luxations of the scapulohumeral joints are seen. Osteochondrosis may be present in the form of cartilage flaps of the humeral head or cystlike lesions of the glenoid of the scapula. Osteoarthritis is usually secondary to trauma or OC and typically shows a flattening and elongation of the humeral head with subchondral sclerosis of the glenoid of the scapula.

Ultrasoundography can be successfully used to diagnose alterations in the biceps tendon and bursa. The sheath may contain an abnormal amount of fluid, and there may be calcification in or around the tendon. Scintigraphy may provide additional information on the scapulohumeral joint (Fig. 75-20). The chronically affected joint usually develops intense uptake adjacent to the actual joint space. But in some cases, negative contrast is found. Subchondral cystic lesions usually produce increased focal accumulation of the bone label. The attachment of the joint capsule may show increased uptake. Focal uptake can also be observed in the caudal region of the greater tubercle, representing insertion problems of the infraspinatus muscle or bursitis (bursa infraspinati). The proximal cranial aspect of the humerus may be the site of enhanced, mostly clearly delineated uptake, representing inflammatory disorders of the bicipital bursa or the biceps tendon.

Fractures of the deltoid tuberosity are not always localized clinically, but on scintigrams will show up as a region of intense uptake.

**Femoropatellar and Femorotibial Joints**

A caudocranial and a mediolateral (or lateromedial in the standing horse) view are the standard imaging projections. When using a cone of 8 cm in diameter, two sets of caudocranial images are necessary to image both the joint and the patella. Additional oblique views to image the femoral condyles and the tibial plateau can be added.

The most common radiographic findings include fractures of the patella, tibial plateau, or intercondylar eminence; osteochondrosis; and osteoarthritis. Osteoarthritis is often secondary to meniscal injuries and cruciate ligament ruptures. The radiographs of the stifle are viewed to identify an abnormal amount of soft tissue, changes in the bony contours, and bone density. An increase of the soft tissue shadow may be caused by periarticular swelling or distended joint capsules. Increased articular filling of the femoropatellar joint can sometimes be observed. The outlines of the bones may be disrupted by an avulsion fracture at the attachment of ligaments or fractures of the patella or the tibial crest. The contour of the trochlear ridges can be impaired by OC. Irregular contours of the lateral trochlear ridge are commonly found accompanied by flakelike fragments and irregular bone density in the affected region. Subchondral cystic lesions are commonly found in the medial femoral condyle as circular or ellipsoid radiolucent areas. The borders may be more radiodense. Cystlike lesions in the lateral condyle or the tibial plateau are rare. Most cystlike lesions have a connection to the articular space. The articular surface may be flattened or indented.

The attachment of the cruciate ligaments can be easily observed on the lateral views. Alterations of the bone margin and its structure of the medial eminence are convincing signs of tearing of the cranial cruciate ligament (Fig. 75-21). Often, avulsion fragments are also observed. Damage to the ligaments results in joint instability and produces fibrillation of the articular cartilage. The consequence is formation of articular marginal osteophytes, which can best be viewed on caudocranial projections. The outlines of the eminence may be quite heavily modified by bony outgrowth. At the margins of the tibial and femoral articular surfaces, rounded bone proliferations can be seen. Loose bony fragments may be seen in the femoropatellar or the femorotibial joint. They result either from avulsion fractures or OC.

Infections of the femoropatellar or femorotibial joint occur most commonly in foals. The result is increased synovial filling of the femoropatellar joint, causing a larger joint

---

Figure 75-20. Scintigraphic image of the shoulder region of a horse with sudden unwillingness to jump obstacles. Radiographs were normal. There is a focal increased accumulation of the bone tracer in the region of insertion of the supraspinatus muscle and the lateral ligaments. Acute tearing of these insertions was suspected.
space between the patella and the trochlear ridges. The enlarged joint capsule may become visible. In later stages of the infection, circular lytic regions may develop in the subchondral bone.

Ultrasonography is useful in evaluating the medial and lateral collateral ligaments, the patellar ligament, the cruciate ligaments, and the menisci. The bony contours, especially the cartilage of the trochlear ridges, can also be assessed quite easily.

Bone imaging of the femoropatellar or the femorotibial joint is very rewarding, since many discrete alterations can be visualized. It is best performed in the anesthetized animal, which allows acquisition of high count numbers and the use of collimators for better resolution.

Figure 75-21. Lateral (A) and caudocranial (B) scintigraphic images of a femorotibial joint of a horse with chronic intermittent lameness. There is increased uptake in the femoral condyles in the lateral projection, which can be localized to the medial side when the caudocranial view is added. There is also increased tracer uptake on the medial aspect of the tibial plateau and the intercondylar eminence. On the lateromedial radiograph (C), a caudal displacement of the tibia is noted, which is characteristic for anterior cruciate ligament rupture. On the caudocranial radiograph (D), osteophytes at the medial aspect of the femorotibial joint (white arrow) indicate osteoarthritis.
Occult subchondral bone cysts usually produce focal areas of intense uptake. The attachment of the cruciate and meniscal ligaments can be visualized. Osteoarthritis produces increased uptake at the joint margins. It is very important in the evaluation of femoropatellar and femorotibial joint problems to obtain two scintigraphic views: a lateral and a craniocaudal. The patellar ligaments also may provoke accumulation of the bone label at their attachment sites.

**Coxofemoral and Sacroiliac Joints**

Several techniques have been described in the literature for the demonstration of the coxofemoral articulation in the standing horse. All result in a high radiation burden for the assisting personnel. Image quality is usually impaired by the choice of the fast intensifying screens, which have to be used to avoid patient movement. The use of a scatter grid is not possible. Therefore, it is strongly suggested that this examination be performed only in the anesthetized horse, where the patient can be positioned onto the imaging system allowing a true ventrodorsal projection. This view can be completed by additional oblique views of the coxofemoral joint. The side under examination is lowered onto the image plate. Use of x-ray beam limiting devices such as a cone greatly increases the details in the image, but positioning becomes critical. When the horse is lying on its back, the cleft in the gracilis muscle can be palpated. A point of this cleft about 10 to 12 cm from the midline serves as a landmark for centering the x-ray beam onto the coxofemoral joint.

In the normal horse, the acetabular structures and the femoral head can be seen. In the acetabulum, a shallow groove can always be discerned. In the normal articulation of the femoral head, a radiolucent area is visible where the round ligament is attached.

Arthritic changes are sometimes observed in the form of enthesiophytes. These may deform the articular head and the articular margins (Fig. 75-22). The bone density and the articular contour may become irregular. Very often, the attachment site of the round ligament becomes more pronounced. Cystlike lesions also have been observed at the site of the capital femoral physis.

Epiphyseal detachment (traumatic epiphysiolysis) is usually diagnosed before epiphyseal closure, but sometimes it is observed even after closure in well-developed colts and fillies.

The radiographic examination of the coxofemoral region should always be preceded by a pelvic overview image, allowing interpretation of the adjacent bony structures. Fractures of the ischium, ilium, tuber sacrale, and other pelvic structures may be diagnosed. Fractures of the ischiatic process and the third trochanter may mimic hip joint disorders. Luxations of the femur are rare events and usually easily diagnosed by the displaced femoral head.

Scintigraphic evaluation of the pelvis is particularly useful because of the limitations of radiography (Fig. 75-23).

The local activity and the shape of the anatomic landmarks are compared. The sacroiliac joints, the tuber ischii, the lumbosacral joints, and the tuber coxae are most frequently affected. High focal uptake of the bone label in the sacral region is not infrequent. Fissures do occur in the

Figure 75-22. Coned-down radiographic view of the coxofemoral joint of a Friesian stallion. Severe osteoarthritis is indicated by flattening of the femoral head (arrows), and by marked osteophyte production on the acetabular rims (a and b). Interestingly, the horse was only moderately lame.

Figure 75-23. A, Bone scan of the sacroiliac region. The increased uptake in the medial aspects of the sacroiliac joints is more pronounced on the left side. B, Ventrodorsal radiograph of the same area documents osteophyte formation, joint irregularity, and enlargement of the sacral wings (arrowhead), more evident on the left side.
proximal half of the femur, producing linear increased uptake patterns. Fracture of the third trochanter provokes high focalized activity. Enostosis in the femur is visualized by intense focal uptake.

**Spine**

The techniques used for the radiographic visualization of the equine spine vary for different regions. For the cervical spine, the examination is best performed in the standing animal. The quite large and broad cervical vertebrae have a more normal position in the standing horse. Distortion as a result of oblique positioning of the vertebrae may occur under anesthesia but can be avoided. With the horse standing, it also is possible to obtain oblique views of the cervical column, which make interpretation of the cervical facet joints much easier.

Usually, the horse is slightly tranquilized. A cassette stand is used for holding the cassettes in place. For the lateral views, a scatter grid and screens of medium speed are advisable. When using a cassette size of 30x40 cm, three views are necessary to cover the entire cervical column. The first view is centered on the articulation of the first and second vertebrae, the second view on the fourth vertebra, and the third on the intervertebral joint of C5-6. The oblique views are made at an angle of 45 to 55 degrees to the x-ray tube, either from below or from above. It is advisable to take the oblique views of the cervical spine from both sides.

In foals, malformation of the occiput and the first and second vertebrae have been observed and reported in the literature (see Chapter 51). The involvement of the different vertebrae and the degree of the malformation vary. Malformations are reported to occur in some Arabian families. The authors have seen some cases in Warmblood horses. Fracture of the dens of the second vertebra occurs in the young animals, usually along the unfused physis as a sequela of trauma. Subluxation may be observed between the first and second and between the third and fourth cervical vertebra. The extent of the abnormal angulation is the decisive diagnostic criterion. Small angular deviations seem to have no significance, whereas larger ones usually cause cervical stenosis and impairment of the spinal cord (wobbling).

Common radiographic findings in adult horses are enlargement of the joint facets, especially in the lower cervical region, subluxations, OC-related arthritic changes, and osteoarthritis.

In young animals, malformations are mostly seen in the proximal cervical spine. Fractures of the vertebral bodies or the articular processes are observed occasionally. In horses with ataxia and forelimb lameness, the enlargement of the facet joints in the last three vertebrae plays an important role (Fig. 75-24). The incidence of such lesions and the correlation with the clinical signs are very high.28,29 Suspected space-occupying lesions (e.g., enlarged joint capsules of the facet joints) can be further evaluated by myelography.

Only the spinous processes of the thoracic spine can be radiographed in the standing animal. Many clinicians are satisfied with these images, but the thoracic spine is not well investigated by this method. If more details are desired, the examination has to be performed in the anesthetized horse in lateral recumbency. Because large masses of soft tissue have to be penetrated by the x-ray beam, scatter radiation is a big problem. Therefore, a two-step examination using smaller exposure fields and scatter grids is strongly recommended.30,31 Fine-to-medium screens can be used to demonstrate the spinous processes in the saddle region. Normally, these articulations are less visible because of the absorption of the gamma rays by the large muscle mass in this region. Radiographically, the dorsal intervertebral articulations of C6-7 are enlarged and sclerosed, and the joint space is irregular and narrowed. The intervertebral foramen is also narrowed.

In adult horses, malformations are mostly seen in the proximal half of the femur, producing linear increased uptake patterns. Fracture of the third trochanter provokes high focalized activity. Enostosis in the femur is visualized by intense focal uptake.

Therefore, a two-step examination using smaller exposure fields and scatter grids is strongly recommended.30,31 Fine-to-medium screens can be used to demonstrate the spinous processes in the saddle region. In the more posterior parts of the spine, the highest screen speeds are important. Only small fields are exposed (10x30 cm); the cassette is shielded with lead plates to eliminate scatter radiation from reaching the film. The x-ray beam is partially attenuated by a specially formed filter (SAAB Dodger, Trollhättan, Sweden). To demonstrate the intervertebral articulations, only a narrow strip of the 30x40-cm cassette is exposed. Together with the scatter grid and high-speed screens, it is possible to visualize the articular structures. To cover the most affected regions of the thoracic spine, usually three views of 30x40-cm film are necessary. Positioning of the animal is important to reduce distortion of the spine and superimposition of the rib cage. Only the three cranially situated vertebrae of the lumbar spine are demonstrable. The caudal part is overlaid by the pelvis.

**Figure 75-24. A,** Bone scan of the lower cervical spine. The dorsal intervertebral articulation of C5-6 and C6-7 accumulates the tracer. Normally, these articulations are less visible because of the absorption of the gamma rays by the large muscle mass in this region. Subluxation may be observed between the first and second and between the third and fourth cervical vertebra. The extent of the abnormal angulation is the decisive diagnostic criterion. Small angular deviations seem to have no significance, whereas larger ones usually cause cervical stenosis and impairment of the spinal cord (wobbling).

**B,** Radiographically, the dorsal intervertebral articulations of C6-7 are enlarged and sclerosed, and the joint space is irregular and narrowed. The intervertebral foramen is also narrowed.

Positioning of the animal is important to reduce distortion of the spine and superimposition of the rib cage. Only the three cranially situated vertebrae of the lumbar spine are demonstrable. The caudal part is overlaid by the pelvis.
The principal radiographic signs of changes of the spinous processes consist of deformations, narrowing of the interspinous spaces, sclerotic borders, facet formation, and spinal arthritis. In advanced cases, debris cysts and vacuum phenomena may also be observed.

The alterations of the intervertebral joints include the usual radiographic findings of subchondral sclerosis, irregular joint spaces and margins, enlargement of the articular surfaces, subchondral radiolucent areas, and in some horses, even ankylosis. The most affected vertebrae are the last three thoracic ones.

The sacroiliac region can be radiographed only in the ventrodorsal projection under general anesthesia. The imaging system with a scatter grid is placed under the horse and the horse turned onto it. The intestines can be moved by forced ventilation during the exposure. More powerful x-ray generators allow prolonged exposure times of up to 5 seconds. This allows at least two forced expirations. With this procedure, the margins of the intestines with their contents become blurred. The sacral wings of the pelvis and the lumbosacral joints can be observed. Enlargement and gross alterations of the contours of the sacral wings are very common. Changes of the lumbosacral joints consist of irregular articulations and subchondral sclerosis. Sometimes, even the dorsal intervertebral joints of the last lumbar vertebrae are visible and can be inspected.

Indications for bone imaging of the spine include clinical signs such as painful back, loss of performance in jumping and dressage horses, and lameness in the hindlimbs. General anesthesia is necessary, as is the use of high-resolution collimators and high total count numbers.

The lumbar and thoracic spine is demonstrated by dorsal oblique views. It is recommended that the camera be placed on the right side to avoid superimposition of the right kidney over thoracic vertebrae structures. Very small anatomic details can be demonstrated with the HRLE collimator at 2,000 k for the lumbar spine and 3,000 k for the posterior thoracic spine. It is not necessary to examine the spine from both sides.

In the lumbar spine, the uptake pattern (focal increased uptake) and the shape of the dorsal and lateral processes are investigated. Very frequently the fourth and fifth dorsal spinous processes show high focal uptake when they are contacting each other. Very often, the uptake of the kidneys disturbs the interpretation of the lumbar and thoracic spine. Modern nuclear medicine computers permit drawing an ROI around the kidneys, which can then be subtracted from the image, allowing better visualization of bone structure.

The most frequent pathologic finding is increased uptake in the sacroiliac and lumbosacral joints. Ankylosis of the dorsal intervertebral joints occurs first in the lumbar spine. Trauma to the lumbar spine (e.g., fracture) may produce very intense circumscribed accumulation within the affected region.

The thoracic spine is the most affected part of the equine back. Two different structures seem to play an important role in the equine back pain syndrome: the spinous processes and the dorsal intervertebral joints. The alterations of the spinous processes consist of deformation, enlargement of the proximal part, and increased focal or bifocal uptake at the sites where new joints are formed or overriding of the spinous processes occurs. Increased joint activity can be observed affecting the whole joint by producing one single area of activity. As a second pattern, sometimes increased activity in either one or both joint facets producing one or two smaller focal uptake areas is seen. Ankylosis of joints occurs mostly in the posterior section of the thoracic spine. In the bone scan, this can be perceived by enlargement of the joint or formation of an extra-articular bridge. The highest frequency of joint alterations is observed between the 15th and the 17th thoracic vertebrae. Alterations of the spinous processes are most frequently seen in the region of 13th to 16th thoracic vertebrae.

Interpretation of the true bone activity is sometimes very difficult, especially when the whole spine shows increased tracer accumulation. For a more objective evaluation, a special ROI technique has been developed. A reference ROI is placed on the middle part of the 16th or 17th rib. Subsequently, ROIs of similar size are defined over the intervertebral joints and the spinous processes. The actual size of the ROIs is not very important, because only the average values (total counts of a specific ROI per number of pixels in the ROI) are used. The uptake ratio of a particular joint is obtained by dividing it by the reference ROI. In normal horses, the uptake ratios for the dorsal intervertebral joints are less than 2.0, and the spinous processes have values less than 1.5.

In the recumbent animal, the cervical spine can be examined with the high-resolution or a GP collimator. The resolution of the GP collimator is not as good as that of the HRLE. The dorsal intervertebral joints can be evaluated by bone scans. The activity of the joints of C5 through C7 should be less than of the joints in the more cranial region because of the attenuation by the overlaying muscle mass. High activity in the lower cervical spine represents active arthropathy. Quite often, the joint surfaces are so enlarged that this can be recognized in the bone scan.
REFERENCES

Magnetic resonance imaging (MRI) uses the hydrogen protons in the body to produce detailed images of bone and soft tissue structures. The images (slices) that are obtained can provide a variety of different information from the same anatomy by varying the imaging sequences. Depending on the type of lesion suspected, different imaging sequences are chosen to highlight a specific tissue type. A typical protocol used to look at anatomy and pathology in the distal limb of a horse is composed of a variety of sequences. In this way, visualization of inflammation, edema, or irregularity of signal in soft tissue structures and bone is possible. Because the MRI unit generates a radiofrequency pulse that is specific to hydrogen atoms, it is capable of detecting subtle abnormalities in tissues when the field strength of the magnet is greater than 1.0 tesla.

Magnetic resonance imaging is a continuously evolving technology because the imaging techniques and slice planes are constantly being refined. Initially, MRI sectional anatomy was described for the equine foot and metacarpophalangeal regions using cadaveric limbs. However, as more detailed information regarding sectional anatomy and observations of pathology in the distal limb has been related to lameness in live horses, this technology has achieved practical clinical application. MRI is extremely complex, and the goal of this chapter is to provide an introductory basis for understanding it in a clinical environment as it applies to equine lameness diagnoses.

PHYSICS OF MRI
Magnetic resonance results from the effect of magnetic properties of atoms found in biologic tissues. These atoms consist of a central nucleus containing both protons and neutrons, surrounded by orbiting electrons. The spinning motion of specific nuclei in tissue, called MR active nuclei, form the basis of MRI. These spinning nuclei acquire a magnetic moment, enabling them to interact with an external magnetic field. The positive charge of protons and the spinning motion generate a magnetic field of their own.

The most common MR active nucleus found in all tissues is that of the hydrogen atom, which contains one positively charged proton. The abundance of hydrogen in tissue and its relatively large magnetic moment make it the optimal choice for clinical MRI. Because of the high concentration of available hydrogen in fat and water, these substances contribute the majority of the signal in MRI. When an animal or its extremity is placed into the bore of a magnet, all the available hydrogen atoms that are normally randomly oriented align with the external magnetic field. At this time, a short-duration radiofrequency pulse that can be programmed to disrupt the aligned protons is applied to the area. This disruption will be best when the pulse has the same frequency as the aligned protons, causing generation of a signal through an exchange of energy. From the collected signals, images are obtained. Signal intensity is shown on the images in grayscale, where high-signal areas are white and low-signal areas are black.

A multitude of pulse sequences can be created to highlight specific tissues by modifying the signal intensity, but sampling time and image quality must be taken into consideration when determining the optimal sequences to use. The collected signal is called an echo, and it is detected by a radiofrequency receiver coil placed around the tissue of interest. Multiple echoes are necessary to provide all the information necessary to create an MR image. Fast spin echo sequences are typically used in horses to shorten scan time and reduce the length of time under general anesthesia. Magnetic field gradients within the magnet allow tissue sampling in a chosen orientation. This creates the ability to look at one slice at a time. With MRI, the generation of an image of a specific, thin cross section of the body is possible. These slices can be obtained in standard anatomic planes (e.g., transverse, sagittal, dorsal), or the slice plane can be oriented in any direction through the horse’s limb. The number of slices and the thickness of the slices can also be varied. Additional information on MRI physics is found in Chapter 75.

APPLICATION TO THE HORSE
Magnetic resonance imaging has been routinely used to evaluate horses with lameness problems in the distal limb at Washington State University Veterinary Teaching Hospital since 1997. In the last 8 years, MRI has proven to be a valuable diagnostic tool for making specific diagnoses in horses with performance-limiting lameness problems in the distal limb. It is especially valuable in the equine foot because it allows evaluation of soft tissue structures within the hoof capsule that are difficult to visualize with other imaging modalities. It also allows multiplane images through the foot, enabling soft tissue and bone structures to be seen in ways not previously possible.

Radiography has for a long time served as the gold standard for evaluating horses with lameness localized to the foot, providing excellent evaluation of osseous structures but minimal information on soft tissue structures. Ultrasonography of the foot is limited because of the hoof capsule and the difficulty in achieving good scan-head contact through the sole or frog. Nuclear scintigraphy (see Chapter 75) can be used to evaluate the foot, but it is of limited value in detecting abnormalities in soft tissue structures and in detecting small areas of abnormalities in the bone; it is best for finding fractures and acute bone injuries that involve enough bone that increased metabolic bone activity can be detected. When compared with scintigraphy, MRI is more sensitive and specific for both bone and
soft tissue injury. High-field magnets (1 to 1.5 tesla) are able to image forelimbs of horses from the foot to the distal radius, hindlimbs from the foot to the distal tibia, and the head to the first few cervical vertebrae. It is also possible to image most other areas in small foals or miniature horses.

Image quality and resolution increase with increasing magnetic field strength, so high-field magnets have more detailed images than low-field magnets. "Open" magnets have an opening along one side of the magnet. However, magnetic field strength is most uniform in "closed" magnets, which are cylindrical, with openings at both ends. Therefore, image quality is superior with closed, high-field magnets when compared with low-field open or closed magnets. High-field magnets of 1.0 tesla or higher are necessary to obtain quality images in live horses.

LOGISTICS OF MRI FOR HORSES

Magnetic resonance imaging of horses requires general anesthesia if a high-field magnet is used. Image quality deteriorates when the area being imaged is not within the isocenter of the magnet. High-field magnets designed for humans have a long, narrow bore that makes it difficult for the limbs of a horse to be placed in the isocenter. However, high-field, short-bore magnets with flared ends are available that allow the horse’s limbs to be better positioned. Therefore, imaging of the proximal limb is limited only by how far the horse can be pulled into the magnet. For horses with shorter limbs and thicker bodies, it may be possible to provide more room by removing the table from within the bore of the magnet.

Horses undergoing MR scanning must have all shoes and nails removed to avoid artifacts from ferrous material. If feet are being scanned, a 60-degree dorsopalmar radiograph must be taken prior to scanning to avoid artifacts from small pieces of horseshoe nails that might be left in the hoof wall after the shoes are removed. All limbs are placed in obstetrical sleeves to decrease debris in the magnet. Thorough cleaning of the frog sulci and sole of the foot is needed to prevent foreign material from causing magnetic susceptibility artifacts.

High-field magnets are constructed in a room shielded from radiofrequency waves, and ferromagnetic material cannot be used. Horse transport tables are currently custom built without ferromagnetic materials, but with the capability of supporting horses weighing up to 2000 pounds. Anesthesia equipment should contain as little ferromagnetic material as possible and have a position in the shielded room that is far enough from the magnet so as not to interfere with the magnetic field. Induction and transport of horses to and from the magnet requires a team of experienced people. The horse can be maintained on injectable anesthetics during transport and then connected to a vaporizer once in the shielded room.

CASE SELECTION

Magnetic resonance imaging is indicated when other diagnostic modalities fail to yield a diagnosis of the horse’s lameness problem. Although MRI provides useful information in many clinical conditions, the authors have restricted its use to horses with lameness problems that are localized to an anatomic area but that do not have radiographically or ultrasonographically detectable abnormalities. This has been implemented because of the length and expense of the procedure and the need for general anesthesia. It is important to localize the source of the lameness prior to performing MRI, because the length of time required to image one area of the distal limb and the contralateral limb is approximately 45 to 60 minutes. Additional time is required for anesthetic induction, transport, and positioning of the horse in the magnet. Scanning more of the horse’s limb than is necessary not only increases the time to perform the sequences but also requires repositioning of both the coil on the limb and the horse within the magnet. Therefore, prolonged anesthesia can be avoided if a lameness examination with diagnostic blocks is used to localize the source of the problem in the distal limb of the horse.

IMAGING PROTOCOLS

Until more experience with MRI of horses improves the present knowledge of variations of normal, MRI should always be performed on both limbs, even in horses with a unilateral lameness. This allows the evaluator to compare the affected limb to the contralateral limb.

The standard protocols include proton density (PD), T2-weighted (T2), short tau inversion recovery (STIR), and three-dimensional gradient echo (3D) sequences (Table 76-1). *Proton density* sequences provide images that clearly show anatomic structure, and therefore they are the easiest images to evaluate for ligament and tendon symmetry. These images display any change in the density of protons as a change in signal intensity, causing each tissue to produce different signal intensities. *T2-weighted* sequences produce images with high fluid contrast but minimal shades of gray, resulting in an image that is more difficult to evaluate for definition of soft tissue structures. *T2-weighted* images are useful when looking for fluid within soft tissues and for determining whether areas of high signal within soft tissue are fibrous tissue or inflammatory fluid. *Short tau inversion recovery* sequences produce images that are of high contrast and low clarity, but they provide the best sequence for finding fluid within bone and soft tissue structures. This sequence is useful for diagnosing inflammatory bone lesions. *Gradient echo* sequences produce images with good definition of bone structure but poor definition of some soft tissue structures. These can be set up with or without fat suppression and are the most time-efficient scans to run. Areas of fluid within the bone may be seen with these scans, but they are not as sensitive as the STIR sequences.

The majority of MRI series performed in the horse have been done on the foot, phalangeal, metacarpophalangeal (MCP) and metatarsophalangeal (MTP), and metacarpal and metatarsal regions. This chapter describes pathologic abnormalities observed in horses limbs distal to the carpus and tarsus.

MRI OF THE FOOT

Magnetic resonance imaging has allowed veterinarians to understand the interrelationships of the internal soft tissue structures in the horse’s foot for the first time. In addition to
soft tissue structures, the ability to section the limb in any plane has also allowed better visualization of the osseous and synovial structures in the equine foot. All of this has improved the ability to derive specific diagnoses in horses with lameness problems originating in the foot and has led to better treatment decisions and case management.18

Deep Digital Flexor Tendinitis

The deep digital flexor tendon (DDFT) is a low-signal (black), well-defined structure with two symmetrical lobes that become fan shaped at their insertion onto the distal phalanx. Lesions in the DDFT are typically found at three locations in the foot of the horse: the insertion to the distal phalanx (Fig. 76-1), at the level of the distal sesamoid bone (DSB)14 (Fig. 76-2), and proximal to the DSB. Horses may suffer from lesions at one, two, or all three locations at one time, and some have lesions extending from the insertion on the distal phalanx proximally to the MCP joint.

Deep digital flexor tendon lesions are commonly seen as high-signal (white) areas within the tendon (core lesion), as roughened, irregular surfaces along the dorsal edge of the tendon, or as small vertical splits that are often located at the insertion of the DDFT or at the level of or proximal to the DSB. Lesions can also be seen as an enlargement of the tendon in which the signal remains low but tendon thickening or an irregular shape is observed. The high-signal lesions are usually well defined and run longitudinally within the tendon, in one or both lobes, and there is typically enlargement of the tendon (Fig. 76-4).

Deep Digital Flexor Tendinitis

The deep digital flexor tendon (DDFT) is a low-signal (black), well-defined structure with two symmetrical lobes that become fan shaped at their insertion onto the distal phalanx. Lesions in the DDFT are typically found at three locations in the foot of the horse: the insertion to the distal phalanx (Fig. 76-1), at the level of the distal sesamoid bone (DSB)14 (Fig. 76-2), and proximal to the DSB. Horses may suffer from lesions at one, two, or all three locations at one time, and some have lesions extending from the insertion on the distal phalanx proximally to the MCP joint.

Deep digital flexor tendon lesions are commonly seen as high-signal (white) areas within the tendon (core lesion), as roughened, irregular surfaces along the dorsal edge of the tendon, or as small vertical splits that are often located at the insertion of the DDFT or at the level of or proximal to the DSB. Lesions can also be seen as an enlargement of the tendon in which the signal remains low but tendon thickening or an irregular shape is observed. The high-signal lesions are usually well defined and run longitudinally within the tendon, in one or both lobes, and there is typically enlargement of the tendon (Fig. 76-4).

Tendinitis of the DDFT is a common finding in horses that present with heel pain. Affected horses may show a unilateral or bilateral lameness with clinical signs that mimic navicular disease. In many cases, this is the primary abnormality observed with MRI. Horses that suffer from tendinitis without DSB abnormalities have treatment options that differ from those of horses with chronic DSB degeneration.

TI for STIR sequences is 140 msec; the T2 and PD sequences are collected together during the TSE scan.
FA, flip angle; FOV, field of view; Gap, space between slices; PD, proton density; rFOV, relative field of view; STIR, short tau inversion recovery; TE, echo time; Time, actual scanning time for each sequence; TR, repetition time; TSE, turbo spin echo; T2, T2-weighted; Width, thickness of slice; 3D GE, three-dimensional gradient echo.

18. Deep digital flexor tendon lesions are commonly seen as high-signal (white) areas within the tendon (core lesion), as roughened, irregular surfaces along the dorsal edge of the tendon, or as small vertical splits that are often located at the insertion of the DDFT or at the level of or proximal to the DSB. Lesions can also be seen as an enlargement of the tendon in which the signal remains low but tendon thickening or an irregular shape is observed. The high-signal lesions are usually well defined and run longitudinally within the tendon, in one or both lobes, and there is typically enlargement of the tendon (Fig. 76-4).

Tendinitis of the DDFT is a common finding in horses that present with heel pain. Affected horses may show a unilateral or bilateral lameness with clinical signs that mimic navicular disease. In many cases, this is the primary abnormality observed with MRI. Horses that suffer from tendinitis without DSB abnormalities have treatment options that differ from those of horses with chronic DSB degeneration.
Figure 76-1. Axial proton density images through the distal phalanx and the deep digital flexor tendon (DDFT) proximal to its insertion on the distal phalanx. A, The lame left front foot has abnormal high-signal intensity (arrow) as a result of a tear in the medial aspect of the DDFT. B, The normal right front foot for comparison.

Figure 76-2. Axial proton density sequences from a horse with a right front limb lameness that blocks to a palmar digital nerve block. A, The normal left front foot for comparison. B, A full-thickness, high-signal-intensity vertical tear is seen in the enlarged bundle of the deep digital flexor tendon of the right front foot (arrow). The sections are through the distal aspect of the middle phalanx and the distal sesamoid bone of both feet.

Figure 76-3. Axial proton density images through the proximal aspect of the middle phalanx from a horse with right front limb lameness. A, The normal left front foot for comparison. B, There is abnormal high-signal intensity in the deep digital flexor tendon (arrow) of the right foot and increased fluid in the digital flexor tendon sheath.
Observations in Horses with Clinical Signs of Navicular Disease

**Distal Sesamoid Bone, Fluid, and Sclerosis**

In many horses with navicular disease, abnormal fluid is observed in the DSB. The fluid can be classified as mild to severe based on the amount observed. *Bone edema* is a term that is used to describe abnormal fluid within the DSB. It is most visible when the high signal of fat is suppressed, as in the STIR imaging sequences (Fig. 76-5). Fluid accumulates in areas of inflammation, and the high signal from fluid in the bone is likely to be the result of inflammation. In horses with acute lameness, the fluid may be caused by bone injury—for example, hemorrhage secondary to a contusion.

In the DSB, fluid is most often seen at its distal aspect proximal to the insertion of the impar ligament (IL) (Fig. 76-6). The accumulation of fluid commonly extends proximally along the palmar half of the bone to the insertion of the navicular suspensory ligament (NSL). More severe involvement of the DSB results in diffuse fluid throughout the medullary cavity.

Low-signal intensity (black areas) is indicative of bone sclerosis and is observed in the medullary cavity of the DSB on palmarodorsal images. Sclerosis or increased bone density observed in the DSB results from the bone’s response to increased load (Wolff’s Law) or to injury. Horses that suffer from bone injury in other locations, including...
horses with fractures, develop sclerosis or increased bone density around the injury, and abnormal areas of low-signal intensity are observed on palmarodorsal images. Although the cause for sclerosis of the DSB remains speculative, it seems logical that it is a response to repetitive injury. Sclerosis can be observed along with areas of fluid, but it is also seen in bones where no inflammatory fluid is present. In a DSB that has undergone severe trauma, large portions of the entire bone of one foot are sclerotic. Sclerosis can occur diffusely throughout the DSB (Fig. 76-7), or it can be localized to one area, most commonly in the central region (Fig. 76-8). Some horses have either fluid or sclerosis of the DSB as the only abnormal finding. Sound horses do not have edema or sclerosis in their navicular bones.

Erosion of the flexor cortex (Fig. 76-9) is well visualized with MRI; subchondral defects most commonly occur along the palmar distal half of the bone and are most often seen centrally, or on one (Fig. 76-10) or both sides of the sagittal ridge. Adhesion of the DDFT to the DSB can be clearly observed in some horses, but injection of fluid into the navicular bursa may be necessary to clearly define adhesions in other horses.

**Navicular Suspensory Ligament Desmitis**

One of the abnormalities observed in horses with navicular disease is desmitis of the NSL of the DSB. This is seen as thickening that can be localized either to the body or to...
the collateral branches, or it shows up as a diffuse signal throughout the entire ligament. Enlargement of this ligament is a finding consistent with chronic desmitis. High-intensity in the body of the ligament has been seen in some horses, most commonly on transverse slices, and it is indicative of acute inflammation and/or tearing of the ligament (Fig. 76-11). The acute history in these patients is consistent with a ligament injury.

Thickening of the NSL is also a common finding in horses that have multiple abnormalities associated with navicular disease. Desmitis of the NSL is currently evaluated as mild, moderate, or severe on the basis of the amount of thickening observed in the ligament. Avulsion fracture of the proximal aspect of the DSB has also been visualized with MRI.

**Impar Ligament (IL) Desmitis**

Impar ligament desmitis is another abnormality observed in horses that present with clinical signs of navicular syndrome. Lesions in this ligament are seen as discrete or diffuse high-signal lesions. Thickening of the ligament, with or without changes in signal, also occurs (Fig. 76-12). Abnormal fluid signal is observed at its origin on the distal aspect of the DSB or at its insertion on the palmar or plantar...
distal phalanx. Avulsion fractures at the distal aspect of the DSB have been observed. Irregularity in the IL can also be seen as a part of multiple abnormalities found in horses with navicular disease.

**Navicular Bursitis and Distal Interphalangeal Joint Synovitis**

The amount of fluid in the synovial structures can be evaluated most easily with STIR and T2 sequences. Joint injury, osteoarthritis, and inflammation usually cause synovial effusion. Magnetic resonance images are evaluated for increased fluid in the distal interphalangeal joint (Fig. 76-13) and the navicular bursa (Fig. 76-14). Fibrous scar tissue (adhesions) is observed between the DSB and the DDFT in horses with chronic DSB degeneration and erosion of the flexor cortex. Fibrous scar tissue is also observed in the proximal aspect of the navicular bursa and may be the result of chronic inflammation in this area. Adhesions within the navicular bursa, between the NSL and DDFT or between the IL and DDFT, can be visualized. Navicular bursal fluid distention can also outline adhesions of the DDFT to the flexor cortex of the DSB, as well as defects within the flexor cortex. Fluid distention of the navicular bursa is observed in some horses and is an MRI finding consistent with inflammation and bursitis.18

**Distal Navicular Bone Fractures**

A slice plane oriented from proximal to distal through the DSB allows avulsion fractures to be clearly seen in the insertion of the IL to the DSB (Fig. 76-15). When seen in lame horses, there is fluid at the fracture site indicating active inflammation.
Other Abnormalities Observed in Horses with Lameness Localized to the Foot

Collateral Ligament Desmitis

Damage to the collateral ligaments has been observed in a number of horses with lameness localized to the foot. On the basis of the authors’ experience and that of others,\textsuperscript{19} it appears that this is an important cause of lameness in some horses. Inflammation and fiber disruption cause higher signal intensity within or around the affected ligament (Fig. 76-16), and there may be concomitant bone disruption at the origin or insertion sites. Bilateral desmitis of the collateral ligaments of this joint has been observed in some horses. The medial collateral ligament is affected more commonly than the lateral collateral ligament.\textsuperscript{19}

Osteochondral Abnormalities

Lesions within the subchondral bone show areas of fluid accumulation or sclerosis, indicating injury and inflammation in the bone. At joint surfaces, MRI can define cartilage defects with or without underlying subchondral bone damage that are not visible with radiography.\textsuperscript{9} Synovial fluid

Figure 76-12. Sagittal proton density images from a horse with clinical signs of navicular disease. There is enlargement and irregular diffuse high signal intensity located in the impar ligament (IL) of the left front foot (A) and right front foot (B) (arrows). There is also an area of mild sclerosis in the distal sesamoid bone at the IL attachment in the right front foot (upper arrow in B).

Figure 76-13. Sagittal short tau inversion recovery (STIR) images from a horse that has effusion in the distal interphalangeal joint in the left front foot (A) and right front foot (B). The high signal intensities (arrows) on the image represent synovial fluid in the dorsal and palmar pouches.
Figure 76-14. Axial (A) and sagittal (B) short tau inversion recovery (STIR) images, both of the right front foot, in a horse that has increased fluid in the navicular bursa (arrows). The horse also has deep digital flexor tendinitis, seen on the axial section (short arrow).

Figure 76-15. A gradient echo coronal section through the distal sesamoid bone (DSB) in a horse with a small avulsion fracture (arrow) at the distal border of the right front foot DSB. Fluid in the DSB (arrowhead) indicates inflammation and fluid in the defect.

Figure 76-16. Axial proton density sections through the condyles of the middle phalanx of the left front foot (A) and right front foot (B) show diffuse high signal intensity in the medial collateral ligaments (arrows) of the distal interphalangeal joint.
will enter defects in cartilage, resulting in a high signal within the articular cartilage and in the corresponding subchondral bone when full-thickness articular cartilage damage or defects occur (Fig. 76-17). Trauma to the subchondral bone may occur without overlying cartilage damage, as is seen with bone bruising and trabecular bone microfractures. The high signal in these cases may be caused by hemorrhage in the subchondral bone and medullary cavity.

**Osteoarthritis of the Distal and Proximal Interphalangeal Joints**

Inflammation of synovial structures results in joint effusion, which can be easily visualized with MRI. Periarticular bone proliferation is evident on MR images in sagittal, dorsal, and transverse imaging sequences.

**Penetrating Injuries and Wounds**

Magnetic resonance imaging of horses with puncture wounds in the sole or frog has been beneficial, because it provides an evaluation of affected structures (Fig. 76-18). This is important in making treatment decisions as well as for prognosis. The depth and penetration of the injury can be accurately determined, and the synovial and osseous structures that may have been entered can be seen (Fig. 76-19). MRI has the ability to determine if a laceration has damaged the collateral ligaments of the distal interphalangeal joint or other soft tissue structures in this area.

**MRI OF THE METACARPOPHALANGEAL AND METATARSPHALANGEAL REGIONS**

**Subchondral Bone and Cartilage Damage**

Subchondral bone damage in the MCP and MTP joints has been identified as areas of fluid accumulation in the bone or as sclerosis. Multiple areas of subchondral bone and cartilage damage have been observed in the MCP and MTP joints (Figs. 76-20 and 76-21), although a common location is the palmar or plantar condyle.

Bone bruises show an area of fluid or an area of sclerosis in the bone, but the overlying cartilage can be intact. Fluid accumulation in the bone appears more commonly in acute injuries, whereas chronic bone damage is more frequently

**Figure 76-17.** Axial gradient echo (A) and sagittal short tau inversion recovery (STIR) (B) sections from a horse that has a fluid signal in the subchondral bone of the distal middle phalanx with a chondral defect in the joint surface (arrow). The sagittal proton density image (C) shows the abnormality in the subchondral bone with surrounding sclerosis (arrow) in the same location.
Figure 76-18. Axial gradient echo (A) and sagittal proton density (PD) (B) images of the left front foot of a horse that suffered a nail puncture of the frog. The nail penetrated the deep digital flexor tendon and damaged the flexor cortex of the distal sesamoid bone (DSB) (arrows). The sagittal PD image also shows diffuse sclerosis of the medullary cavity of the DSB.

Figure 76-19. A, Axial proton density section through the condyles of the distal aspect of the middle phalanx of the left front foot shows the marked thickening and abnormal signal observed in the damaged medial collateral ligament and navicular suspensory ligament in a horse with a laceration proximal to the coronary band. B, The more normal right front foot for comparison.

Figure 76-20. Axial (A) and sagittal (B) short tau inversion recovery (STIR) images of the right front limb from a horse with a high-signal-intensity area of fluid in the subchondral bone of the proximal aspect of the proximal phalanx (arrows). An area of osteochondral damage was found on arthroscopic evaluation of the joint.
observed as sclerosis as the bone responds to the injury. These observations with MRI have resulted in an expansion of the concept of bone injury beyond macroscopic fractures. Subchondral bone damage may occur prior to, at the same time as, or after cartilage damage. Bone injuries may likely cause a larger number of lameness problems than was previously thought because most of the subchondral bone lesions observed with MRI are not visible on radiographs. Before MRI was available, these horses were diagnosed as suffering from a soft tissue injury of unknown origin.

**Oblique and Straight Distal Sesamoidean Ligament Desmitis**

The oblique distal sesamoidean ligaments (ODSL) have a homogeneous appearance on MR images, except where they originate from the base of the proximal sesamoid bones. In this area, the ligaments often appear striated with areas of low- and high-signal intensity. Both branches are low-signal, ovoid to triangular structures that form a single structure as they insert on the distopalmar aspect of the proximal phalanx. The straight distal sesamoidean ligaments (SDSL) have a heterogeneous appearance, with multiple low- and high-signal areas spread throughout most of its length. Lesions within the ODSL and SDSL can result in discrete or diffuse high-signal areas within or along the edge of the ligament. Enlargement of the ligament also can occur, usually with a moderate increase in signal density (Fig. 76-22). Desmitis of the ODSL can affect one or both branches (Fig. 76-23). Distal sesamoidean ligament desmitis is not a new cause of lameness in horses, but it was previously difficult to definitively diagnose. Desmitis of the ODSL and SDSL involves injuries that can cause forelimb and hindlimb lameness in many types of performance horses. The lameness varies from mild to severe depending on the amount of damage to the ligament and the duration of the injury prior to diagnosis. Most of these horses do not have a palpable enlargement or swelling over the mid-phalangeal region, so MRI has proven valuable for diagnosing injury to the distal sesamoidean ligaments.81

**Superficial Digital Flexor Tendinitis**

Superficial digital flexor tendon lesions can be diagnosed with MRI in the phalangeal region. These lesions are most commonly seen distal to the bifurcation in the proximal phalangeal region (Fig. 76-24). The tendon gradually separates into two lobes, and lesions in one or both lobes can be observed as high-signal enlargements of the branches of the tendon proximal to its insertion on the middle phalanx.

**Suspensory Ligament Desmitis**

Clinical examination and ultrasonography have been used to diagnose horses with suspensory ligament injuries, a common problem in many types of performance horses. However, MRI has enabled diagnoses that were not possible before, including abnormalities in suspensory ligament branches (Figs. 76-25 and 76-26), insertion of the ligament on the proximal sesamoid bones, and insertion of the proximal suspensory ligament on the third metacarpals and third metatarsal bones (MCIII/MTIII). In the experience of the authors, MRI has proven superior to ultrasound for detecting desmitis in the equine suspensory ligament.

**MRI OF THE METACARPUS AND METATARSUS**

**Proximal Suspensory Ligament Desmitis**

The normal suspensory ligament (SL) does not contact the MCIII/MTIII at any point other than at its origin, and thickening caused by desmitis often results in a decrease or loss of the space between the SL and the MCIII/MTIII. Inflammation of the origin and body of the SL results in
Figure 76-22. A, The normal left front limb for comparison. B, Axial proton density image of a horse with enlargement and an area of high signal intensity (arrow) in the straight distal sesamoidean ligament of the right front limb.

Figure 76-23. A, Axial proton density image of a horse with high signal intensity (arrow) in the lateral branch of the oblique distal sesamoidean ligament in the left pastern region. The abnormal ligament should be compared with the low signal intensity (dark) in the medial branch of the left hindlimb (A) and both branches of the right hindlimb (B), which serves as a normal control. These sections are through the middle aspect of the proximal phalanx.

Figure 76-24. A, The normal left front image for control. B, Axial proton density image of a horse with enlargement of the lateral branch of the superficial digital flexor tendon (arrow) of the right front pastern.
adhesions between it and exostoses of MCII/IV and MTII/IV. Adhesions are visible as low-signal fibers connecting the suspensory ligament to the axial aspect of the vestigial metacarpal or metatarsal bones. In many cases, ultrasonography cannot definitively determine whether adhesions in this area exist. MRI can provide information on the suspensory ligament, location of adhesions, and size of exostoses on the axial surface of the vestigial metacarpal or metatarsal bones. Thickening and linear tears in the suspensory branches and adhesion between the suspensory body and MCII/IV and MTII/IV can be documented (Fig. 76-29).

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Inflammation of the accessory ligament of the deep digital flexor tendon (ALDDFT) is most often seen as diffuse enlargement of the middle to proximal aspect of the ligament, with or without discrete or diffuse areas of high signal. A comparison can be made between the unaffected and the affected limb (Fig. 76-30). Mild desmitis of the ALDDFT is difficult to palpate and the diagnosis is made after MR scanning.

Magnetic resonance imaging enables the definitive diagnosis of a variety of equine distal limb lameness problems. It can be of great value when localization of lameness is not specific enough, or when more information is necessary for the selection of the best treatment modality or an accurate prognosis. MRI can identify lesions not apparent on radiographs or with ultrasonography and can define causes of lameness that can be localized only to an area on the limb. It is an invaluable diagnostic aid for the accurate diagnosis and treatment of equine lameness problems.

Back problems from thoracolumbar soreness in horses have become a frequent complaint in equine practice and represent a challenge for the practitioner. If there are clear radiographic signs of changes at the spine, such as impingement of the dorsal spinous processes ("kissing spines"), spondylopathies of the vertebral bodies, or narrowing of the spinal canal in the cervical area, the diagnosis is relatively straightforward, although the situation is not always easily resolved for the patient. However, in most cases, the cause is more obscure, and pain cannot be easily attributed to changes in the bony skeleton. Complaints of the owners are unspecific and usually consist of problems related to riding rather than lameness. Owners often complain about "unexplainable" resistance of the horses to perform, mental problems of the horses, such as subtle changes of character, and in more severe cases, slight lameness of the hindlimbs or even the forelimbs. In these cases of slight lameness, frequent staggering can become a problem, apart from on-and-off lameness. Very often, owners have sought veterinary help to no avail, especially when radiographs of joints or the spine are normal. Frequently, horses have gone through osteopathic, chiropractic, and acupuncture therapy with a short period of improvement, but the problems are usually not solved in the long term.

Although horses today are kept mainly for horseback riding in leisure or sports activities, veterinarians are reluctant to look into problems related to their use connected to the riding style or equestrian equipment. This may be partly because many equine veterinarians are not horseback riders themselves and simply cannot make educated recommendations. It may also be related to a lack of the courage needed to tell their prospective horse clients that their riding style or equipment needs improvement. Fortunately, antique beliefs that horses do not have back problems have vanished altogether. It is impossible to evaluate today whether horses in older times really did not suffer from back problems or whether symptoms were simply ignored. Nevertheless, the increasing frequency of the complaint of back problems in horses may be related to an increased awareness of horse owners and veterinarians, but also to the attempts of many horse owners to take shortcuts in basic horse education. Therefore, careful training, especially of young sport horses, is neglected. This means that they are not given enough time to learn how to move with a rider on their back, and they are forced into positions of the head and back that the osseous and soft tissue structures of their backs are not quite ready to accept. For example, dressage horses are frequently forced into collection by their owners using all kind of support apparatus in the horse using a transcuneal approach: technique and reference images, Vet Radiol Ultrasound 2001;46:534-540.

In addition, the increasing frequency of back problems in horses may be the result of the modern breeding of horses, which (at least in Warmblood horses) has changed considerably. Not only has the size of horses become enormous (e.g., Hanoverian horses), but also the percentage of Thoroughbred and Arabian blood in their breeding has increased. The huge size of the Warmblood horses renders them in collection more problematic, and the character and mentality of Thoroughbreds and Arabian horses do not permit the forceful riding style that the older type of Warmblood horses seems to have accepted.

Hence, to make an accurate assessment of back pain caused by poor saddle fit, a careful clinical examination...
CHAPTER 77

Saddle Evaluation: Poor Fit Contributing to Back Problems in Horses
Brigitte von Rechenberg

Back problems from thoracolumbar soreness in horses have become a frequent complaint in equine practice and represent a challenge for the practitioner.1-8 If there are clear radiographic signs of changes at the spine, such as impingement of the dorsal spinous processes (“kissing spines”), spondylopathies of the vertebral bodies, or narrowing of the spinal canal in the cervical area, the diagnosis is relatively straightforward, although the situation is not always easily resolved for the patient. However, in most cases, the cause is more obscure, and pain cannot be easily attributed to changes in the bony skeleton. Complaints of the owners are unspecific and usually consist of problems related to riding rather than lameness. Owners often complain about “unexplainable” resistance of the horses to perform, mental problems of the horses, such as subtle changes of character, and in more severe cases, slight lameness of the hindlimbs or even the forelimbs. In these cases of slight lameness, frequent staggering can become a problem, apart from on- and-off lameness. Very often, owners have sought veterinary help to no avail, especially when radiographs of joints or the spine are normal. Frequently, horses have gone through osteopathic, chiropractic, and acupuncture therapy with a short period of improvement, but the problems are usually not solved in the long term.9,10 Although horses today are kept mainly for horseback riding in leisure or sports activities, veterinarians are reluctant to look into problems related to their use connected to the riding style or equestrian equipment. This may be partly because many equine veterinarians are not horseback riders themselves and simply cannot make educated recommendations. It may also be related to a lack of the courage needed to tell their prospective horse clients that their riding style or equipment needs improvement. Fortunately, antique beliefs that horses do not have back problems have vanished altogether. It is impossible to evaluate today whether horses in older times really did not suffer from back problems or whether symptoms were simply ignored. Nevertheless, the increasing frequency of the complaint of back problems in horses may be related to an increased awareness of horse owners and veterinarians, but also to the attempts of many horse owners to take shortcuts in basic horse education. Therefore, careful training, especially of young sport horses, is neglected. This means that they are not given enough time to learn how to move with a rider on their back, and they are forced into positions of the head and back that the osseous and soft tissue structures of their backs are not quite ready to accept. For example, dressage horses are frequently forced into collection by their owners using all kind of support reins, whips, spurs, and other questionable riding gear.

In addition, the increasing frequency of back problems in horses may be the result of the modern breeding of horses, which (at least in Warmblood horses) has changed considerably. Not only has the size of horses become enormous (e.g., Hanoverian horses), but also the percentage of Thoroughbred and Arabian blood in their breeding has increased. The huge size of the Warmblood horses renders them in collection more problematic, and the character and mentality of Thoroughbreds and Arabian horses do not permit the forceful riding style that the older type of Warmblood horses seems to have accepted.

Hence, to make an accurate assessment of back pain caused by poor saddle fit, a careful clinical examination...
should be carried out, and an in-depth anamnnesis of the problems encountered by the rider during riding gathered. Ideally, the horse should also be presented under saddle and tack.

**SIGNS OF BACK PAIN ATTRIBUTABLE TO POOR SADDLE FIT**

Signs of horses with back pain attributable to poor saddle fit may be obvious, such as saddle pressure soresness mainly in the area of the withers. However, most signs are much more subtle and need careful evaluation. Therefore, the first evaluation should be an assessment of riding style.

Regardless of the type of horseback riding used (e.g., English, Western, Spanish), a rider usually tries to ride the horse “in collection.” This means that the horse, in response to the aids given by the rider, bends its head at an angle of 95 degrees to the vertical line of the ground and places the hindlimbs under the rump, resulting in a lifting of the back toward the saddle. In rider jargon, this is referred to as the horse “giving” its back. If a horse is collected properly under the rider, guidance of the horse through fine weight-shifting of the rider in the saddle and subtle signals through the reins becomes very easy and smooth. A well-ridden horse responds to these aids swiftly and at a pull at the reins of only 100 to 200 g. Also, the horse moves forward easily and, in most instances, keeps chewing on the bit, producing visible saliva on its lips.

Unfortunately, often horses are ridden very differently. Riders without patience force the horses to collect, so that they pull their heads down into collection with the reins, using a force up to kilogram levels. Quite often, this false collection is aided by all kinds of support reins. Although these horses may look collected to the observer, in reality the situation is the opposite of being ridden under collection. These horses work against the reins and hands of the rider, and they do not place their hindlimbs under their rump. The gaits of these horses seem choppy, their strides are shortened, and very often their hindlimbs seem to move independently and out of rhythm with the forelimbs. These forceful riding styles can be diagnosed by “counting” the rhythm and looking at the placement of the limbs of the horse, first while being lunged without a rider, and comparing this with the rhythm of the horse moving under the rider. In addition, horses that go against the hand of the rider (or are pulled back forcefully) have pain in the parotid glands when they are palpated. Often, these glands are swollen as well. Especially in dressage horses, forceful riding styles alone can be responsible for horses being unresponsive to given aids, especially after they develop back soreness. However, these signs are presented very often in combination with ill-fitting saddles. Most likely, the ill-fitting saddle is disturbing the muscle action of the back by eliciting undue pressure under the saddle. The horses try to evade the pain through pulling the head up and not bending the back upward toward the saddle. These actions cause shortening of the strides and wrong placement of the limbs during the movements mentioned. An impatient and ignorant rider worsens the problem for the horse considerably. If these horses are ridden with a well-fitting saddle, improvement in movement and riding actions is instantaneous. If a horse is unresponsive to the aids, the rider often refers to a horse as being “hard mouthed” and not “bending” easily into curves or volts (tight circles) required in basic dressage exercises. Therefore, dressage riders, especially, include these symptoms in their anamnesis, together with other behavioral problems of their mounts.

Changes in temperament include frequent and unexplainable attempts of the horse to run off while being ridden. Dressage horses are reported to “hollow the back” from underneath the saddle, which makes it impossible to collect the horse at the reins and bend them smoothly into volts or to perform on a higher level (e.g., the piaffe). It becomes difficult for the rider to elicit smooth transitions between gaits without the horse pulling its head up and losing collection. Often, affected horses become “hard” in the mouth, stop salivating while being ridden, and are difficult to be guided or ridden smoothly. When observed during riding, and especially in collection, horses frequently do not overreach with their hindlimbs (as viewed from the side), and they deviate to one side (mostly to the right side if the rider is right handed) with their hindlimbs (as viewed from the back). If the latter gait abnormality disappears when the horse is ridden with loose reins, it indicates that these problems may be connected to the riding style (e.g., forceful collection) alone. However, if related to poor saddle fit, especially in the lumbar area, the signs usually persist during more relaxed movements. Holding the tail to one side during (or with repeated attempts at) urination may also indicate saddle problems as well as pain. When transitions are made from a collected to a relaxed riding style, horses may pull their heads up instead of stretching their necks and heads forward and downward (in rider jargon, “finding their way to the ground”). However, this may also be related to riding style, with or without a relationship to poor saddle fit. When horses are observed during saddling, they often pull back their ears, move away from underneath the saddle, or, in severe cases, even try to bite the owners.

Close inspection of the hair coat shows broken hair and sometimes swollen hair follicles in particular areas—normally, either the withers or the lumbar area. Both indicate too much pressure, or movement of the saddle, during riding. Muscle atrophy, mainly in the area of the withers or just behind, is often associated with narrow saddles. Soft palpation of the muscles using just the fingertips reveals tension and muscle soreness, especially in the lumbar area. Normal horses do not contract their muscles in response to this type of palpation. Sore spots on the neck, mainly at the interface between the cleidomastoid part of the sternoccephalic muscle and the brachiocephalic muscle, may be attributed to ill-fitting saddles, but they are more often the result of the rider technique (“hard hand”) or the use of support reins (e.g., sliding reins). Finally, dorsiflexion, lateroflexion, and ventral flexion are severely impaired in horses with back soreness.

Back problems caused by the saddle can be associated with the type of riding because they are linked with certain reins, additional aids, and type of saddles. As an example, Western saddles are usually longer than English saddles and, depending on the size of the horse, may cause problems in the lumbar area (Arabian horses frequently have shorter
backs—one less lumbar vertebra—and are therefore ill suited to most Western saddles. The baroque or Iberian style of riding is connected to a specific construction of a saddle (the Spanish type of bar saddle) that distributes the main pressure of the saddle on two main areas (the withers and lumbar areas), which not all horses are strong enough and suited to tolerate without developing back soreness. Additionally, when saddles are bought according to the rider’s preference, and not adapted to the needs of the horse, the saddle may be the center of a back problem. One saddle is often used for several horses, despite the fact that the sizes and the conformations of their backs may be very different (e.g., V-shaped or U-shaped). With racehorses, the saddle comes with the jockey but is never adapted to the young horse.

Ideally, the comfort of both rider and horse should be taken into consideration. A saddle should never be purchased without fitting it to the horse’s back. Ideally, a good saddle maker is present to consider the needs of the rider and the horse. The horse’s back has a certain conformation and cannot adapt to a saddle; rather, the saddle should be adapted to the back of the horse. It is the configuration of the back (where the saddle is positioned), the distribution of the pressure the saddle exerts on the underlying muscles, and the conditioning (or lack thereof) of the back muscles that interact to cause of back problems.

**SADDLE EVALUATION**

Saddle evaluations should start with a good physical examination. The radius of the horse’s back and the curve of the saddle have to correlate well (Fig. 77-1). Freedom for shoulder movement and dorsal spinal processes of the thoracic vertebrae must be allowed with all types of saddles (Fig. 77-2, A). The outward rotation of the saddle tree (or twist) at the front end of the saddle allows room for the shoulder musculature (Fig. 77-2, B). The angle of the saddle cushions should correspond to the shape of the back.

A variety of equipment is available to assist in determining the shape of the back for saddle fitting. The aids range from more complicated computer-driven topographic devices (Saddletech gauges) to simple flexible rods and calipers. This equipment is useful for purchasing a saddle, but generally it cannot be used to evaluate back problems related to poor saddle fit. The most reliable equipment is an electronic saddle mat that allows dynamic pressure
The Pliance mobile 16HE system consists of two thin 2.6-mm saddle mats (dimensions, 169 x 105 x 45 mm), weighing 800 g. These mats are equipped with 112 (English saddle) or 128 (Western saddle) sensors on each side of the saddle that allow measurements between 10 and 60 kPa. The analyzer (Pliance-16 analyzer) is connected to the saddle mats by wires, and it is carried on the rider’s back with a special belt (Fig. 77-3). The data are transferred to the computer either by a computer memory card or via Bluetooth wireless. Several software programs (Novel-Win, Novel GmbH, Munich, Germany) are available for data analysis, each with characteristics that demonstrate one particular feature of the measurements. Either they use two- (Axis, Isobar) or three-dimensional (Mountain Magic) color pictures indicating the individual sensors, or they use curves (Value Master, Emed-sf) over the entire measurement period, where maximal, minimal, or mean values are exhibited (Fig. 77-4). The Novel player allows synchronization with videos taken at the time of measurements. Each program has the ability to show the measured area either as a single, virtually calculated picture or in the time sequence as it was measured in real time. The scanning rate of the sensors is 10,000 frames per second (44 frames per second). Colors (black, blue, green, yellow, pink, red) can be assigned to the pressure values, facilitating interpretation of the data. The maximal pressure picture (MPP) is a virtual picture that gives this value for each sensor during the entire measurement period. The mean value picture (MVP) is the calculated mean value over time and includes all sensors that were loaded at one time. The maximal area picture (MAP) is the frame where the measured area was highest. The maximal force picture (MFP) is the frame where the sum of all forces is the highest.

![Figure 77-3. The Pliance mobile HE16 system mounted on rider and horse. The analyzer is carried on the back of the rider using a special harness, and it is connected to the electronic saddle mat by wires. The measurement is sent to a laptop computer via Bluetooth wireless.](image-url)
Figure 77-4. Different graphics produced by software programs used with the Pliance mobile system. A, Axis. B, Isobar. C, Magic Mountain. D, Value Master, and Emed-sf. Although Axis, Isobar, and Magic Mountain have good visual effects and are well suited to explain pressure values to owners, the Value Master and Emed-sf programs are better suited for scientific analysis.
lumbar area, as identified during the physical examination.\textsuperscript{16} The bridging effect was considered one of the most severe faults in saddle fit. In Western saddles, high pressures were more obvious in the shoulder area, often restricting free movement of the forelimbs.\textsuperscript{21} In race saddles, the peak pressures were often seen over the dorsal spinal processes and directly caudal from the withers. However, even in racehorses, high pressure values were seen in the lumbar area, especially with the training saddles. The occurrence of back pain and other signs in race horses could be correlated to their age of training and also to pressure values found with the saddles.\textsuperscript{16}

Significantly different pressure patterns and high pressure values were always found in saddles with narrow widths of the gullet and missing freedom of the shoulder, not only in the withers but also in the lumbar area\textsuperscript{16} (Fig. 77-10). Significantly lower pressure values were observed with custom-fit saddles than with off-the-shelf saddles. High pressure values were found in horses with neck problems, and with painful cervical and lumbar muscles in association with abnormalities of all flexion tests of the back and the neck. Significant correlations were demonstrated between back muscle atrophy and MPP values, saddle repairs, freedom of the shoulder, and length of the saddle tree. This was also true for saddle pressure and symmetry as well as padding of the saddle cushions. The harder the cushions, the higher were the pressure values. Significant correlations were also found between the caudal positioning of the center of the saddle seat (moved toward the lumbar area) and cervical and lumbar muscle sores. Pain on palpation of the dorsal processes was always correlated with the width of the gullet and caudal positioning of the center of the saddle seat. Problems of the iliosacral joint were associated with the width of the gullet as well as the length of the saddle tree. If supporting aids such as sliding reins were used, forcing the horse into false collection, the pressure values (MPP and MVP) were increased up to 8 kPa (MPP) and 3 kPa (MVP) in the cranial part of the saddle. This pressure increase amounts to approximately 30% of the allowed pressure values for both the MPP and the MVP.\textsuperscript{22}

**OPTIMAL SADDLE FIT**

As a result of the studies with the Pliance system, pressure values for an optimal saddle fit were calculated.\textsuperscript{15,16} If MPP values were lower than 34.5 kPa in the cranial, 30.3 kPa in the middle, and 31.0 kPa in the caudal part, and MVP values were below 13.2 kPa for the cranial, 11.4 kPa for the middle, and 10.0 kPa for the caudal part of the saddles, horses were normally free of saddle-induced back pain. A good saddle shows symmetric distribution of the saddle area, and MAP values greater than 900 cm\textsuperscript{2} during the unloaded phase and 1200 to 1400 cm\textsuperscript{2} during the loaded phase (with the rider). In the loaded phase, the weight of the rider is fully in the saddle, whereas during the unloaded phase, the rider’s weight is not in the center of the saddle (e.g., in posting, in
the swinging phase of the movement). Good saddle panels for the horse’s back are large, they have a soft and even padding, they have no stitches facing the horse’s back, they are wide in the lumbar area, and they optimally are fixed to the saddle body only in the front and the back (see Fig. 77-2). They leave a wide, symmetric gulch of even width from the cranial to the caudal aspect of the saddle. A well-fitting saddle is placed with its front end at the caudal edge of the scapula; the center of the seat should be positioned over the 12th thoracic rib, and the length of the saddle should not reach farther than the last thoracic vertebrae. In smaller horses, such as Arabians, ponies, and Haflinger horses, this may be a problem depending on the size of the saddle seat (which depends on the size of the rider) and the overall construction of the saddle (e.g., a Western saddle).

An optimal saddle fit is difficult or impossible to achieve if the radius of the saddle and the horse’s back do not match. The same is true if the center of the saddle seat is not in the middle part of the saddle but is shifted toward the caudal aspect. This may be related, at least in the English saddle, to the saddle model and the construction of the saddletree (including the head-iron, which determines the fit at the shoulder and over the withers), as well as to the width and height of the saddle gullet in the front of the saddle. In some cases, it may be possible to correct the twist of the saddle, but generally this is not successful. With the shift of the center of the saddle seat toward its caudal aspect, the distance between the suspension of the stirrups and the center of the seat becomes too long (Fig. 77-11). Ideally, this distance does not exceed 1.5 times the width of the hand of the rider. If it is longer, the rider is placed in a so-called chair-seat, which induces unduly high pressures on the horse’s lumbar area and “moves the rider behind the horse.”

This feature is very difficult to correct in a saddle. When the width of the saddle in the shoulder area is too narrow, correction can be made by replacing the head-iron with a new and larger one, as long as the height of the saddle gulch permits it. If it does not, the saddle may touch the dorsal spinal processes of the withers and cause new and severe problems. Sometimes, a saddle correction can be easily made by renewing the saddle panels with new, soft padding. Restuffing the old saddle panels is not recommended, because the padding itself is not of even consistency. In an earlier research study using the Pliance system, it was shown that upholstering the cushions was correlated with higher pressure values and mild muscle sores.

A total of 25 horses presented with back pain were followed after saddle corrections were performed by a skilled saddle maker, or after purchase of a new saddle, and an evaluation was performed with the Pliance system. The absolute pressure values given earlier could be confirmed in this study. If corrections resulted in lower values, the back pain of the horses resolved in all cases, normally within 4 to 6 months after changing the saddles and without any further
treatment modalities. If horses showed severe pain mainly in the lumbar area, the owners were directed to rest them on pasture for at least 4 weeks before riding with the new or corrected saddle was resumed. In most cases, the corrections were most critical for the lumbar area, since corrections normally included a cranial shift of the center of saddle seat away from the lumbar region and toward the middle or wither area of the horse’s back. Although both the corrected and the newly purchased saddles fulfilled these criteria of optimal saddle pressures, the values obtained with corrections of the saddles were better than those of the new saddles. This may just highlight the fact that saddle makers generally have a better knowledge of optimal saddle fit than the salesperson in the average equestrian equipment shop.

In all cases, owners were highly satisfied with the results and commented on the improved motivation, willingness, and ease of their horses to perform according to their wishes.

**SADDLE EVALUATIONS IN EQUINE VETERINARY PRACTICE**

Evaluation of saddle fit in relation to back problems in horses has a definite place in equine veterinary practice. Without a well-fitting saddle, good riding and performance cannot be expected. Since horseback riding is the main reason that horses are kept and brought to the veterinarian, saddle evaluations should be routinely offered in specialized equine veterinary practices. Surgeons, who diagnose obscure lameness in horses, especially when no correlation between radiographic findings and clinical examinations can be found, should also be aware of this. Before horses are subjected to alternative therapies, such as manipulations of the spine using osteopathy, chiropractic manipulations, and acupuncture, a thorough saddle evaluation should be performed by an experienced clinician. The saddle should be inspected from all sides and then placed on the horse to see if it fits properly. The horse should be observed with the saddle and with the rider at a walk and trot. If a computer system that allows evaluation during movement of the horses at the walk, posting and sitting trot, and gallop on both hands is available, electronic pressure measurements can provide objective data and help to identify the reason for the back problems or uncooperative handling during riding.

Once the saddle in combination with riding problems (e.g., false collection) is resolved, the alternative treatment modalities may support the rehabilitation of the horse’s back. However, they can never counteract an ill-fitting saddle or the corrupt riding style of an impatient rider. Although the many corrective saddle pads and wedges available to correct ill-fitting saddles may help to overcome an immediate problem, none of them can replace a genuinely well fitting saddle. Saddles of good quality are normally expensive, especially custom-made ones. However,
owners save money on veterinary care and alternative treatment modalities in the long run. In addition, clients are very grateful to their veterinarians when their horses no longer object to the daily riding routine. In the long run, saddle mats are a sound investment for equine hospitals, especially if the veterinarians have built up a good collaboration with knowledgeable saddle makers, riding instructors, and salespersons of new saddle and riding equipment.

REFERENCES

In horses, the initial treatment of injuries to skin, muscles, joints, tendons, tendon sheaths, and bones greatly affects the chances for perfect healing. Particularly for long bone fractures, a successful surgical outcome is forfeited with improper initial care. Unfortunately, most fractures are exposed to substantial additional trauma during the transportation of the injured horse. In certain situations, it is necessary to use a rescue net and crane or even a helicopter to rescue a horse from a dangerous location. A large-animal rescue unit operating in Switzerland and Liechtenstein specializes in the rescue of large animals involved in automobile accidents or trapped in wells, ditches, gullies, lakes, or rivers.

Rescue efforts can be conducted with the animal standing or in lateral or dorsal recumbency. Rescuing horses is a very complex procedure that must be well planned and calmly executed. A veterinarian experienced with horses should be on hand to prepare and accompany the horse during the rescue operation. Additionally, sedation or short-term anesthesia may be required. Although every rescue operation must be carried out as quickly as possible, time is of secondary importance. In emergency situations, it is imperative to remember that the horse may be in pain, and hastily improvised rescue methods will probably be inadequate and result in additional trauma. For example, narrow, flat, belly bands are painful for the horse and usually fail because the animal slips out of the bands and cannot be rescued or falls out while being lifted, resulting in severe additional injury or even death.

EXAMINATION OF THE PATIENT
A thorough clinical examination is mandatory for horses with fractures. Lacerations or lesions that are overlooked can affect the diagnosis and prognosis considerably. A fracture is often suspected because of the severity of the lameness and the acute onset. When there is doubt, the horse should be treated and handled as a fracture patient. All too often, the assessment of injuries is incorrect, and incomplete and nondisplaced fractures are initially overlooked. This is particularly true in horses that have been kicked in a region where the bone lies directly beneath the skin—for example, the scapular spine, the major tubercle of the humerus, the deltoid tuberosity, the cutaneous plane of the radius, the metacarpus, the metatarsus, the tibia (Fig. 78-1).

TREATMENT OR EUTHANASIA
Despite great advances in veterinary orthopedic surgery and anesthesia, there are several injuries and fractures in horses that can only rarely be treated successfully. When the prognosis is hopeless, the horse should be euthanized immediately. A smooth and quiet euthanasia is of utmost importance for the owner and for potential spectators of the procedure. In all cases, a veterinarian should examine the horse before carrying out the euthanasia.

However, the number of injuries and fractures that have a good prognosis with state-of-the-art treatment is increasing. Radiography is necessary to establish an exact diagnosis as well as to arrive at a prognosis for many fractures. Therefore, adequate emergency treatment is the initial step in the treatment, and the horse is then referred to a clinic that specializes in managing such problems. Once it has been determined that the prognosis is probably favorable and euthanasia is not an option, it is imperative that the patient...
be given the opportunity to receive optimal care and treatment. However, time and time again, horses with fractures are transported without adequate emergency treatment, which not only compromises or eliminates the chance of a successful surgical repair but also is extremely painful for the horse.

Optimal emergency treatment includes the following:

- Initial wound management
- Prophylaxis of infection
- Proper analgesia
- Intravenous fluid therapy
- Sedation and possibly anesthesia
- Stabilization of the fracture
- Careful and safe rescue with proper transportation

Wound Management
Skin wounds must be treated with care. The hair around the wound is removed after covering the wound with water-soluble ointment. Then, a general cleaning of the area is completed with mild soap and water. The wound is cleaned thoroughly, disinfected, and covered with a bandage. A water-soluble antibiotic ointment and sterile dressing should be applied under the bandage. With open fractures, the bone must be cleaned also and covered with a sterile dressing.

Antibiotic Therapy
Immediate administration of systemic antibiotics is indicated in horses with open fractures or large wounds. Otherwise, antibiotic therapy can be delayed until the time of surgery. Antibiotics administered intravenously immediately prior to a surgical intervention achieve effective blood and tissue concentrations within approximately 20 minutes. The regimen of choice is a combination of 30,000 IU/kg of crystalline penicillin and 7 mg/kg of gentamicin sulfate, both administered intravenously. (For details on surgical site infection and antimicrobial use, see Chapter 7.)

Analgesia
Systemic analgesics should be given to the horse as soon as the fracture is stabilized. Nonsteroidal anti-inflammatory drugs such as flunixin meglumine (1.1 mg/kg IV) and phenylbutazone (4 mg/kg IV) may be used. However, when fracture stabilization is inadequate, the use of a potent analgesic is absolutely contraindicated, because this leads to an overload of the injured limb with associated complications. On the other hand, in many cases, good stabilization of the fracture relieves the pain, and analgesics are not necessary.

Intravenous Fluid Therapy
Fractures are rarely associated with severe hemorrhage. However, pain and shock lead to a substantial loss of fluid, which should be replaced using intravenous fluid therapy. After an indwelling intravenous catheter is placed and secured to the skin, a solution of electrolytes and glucose (up to 10% of body weight) should be administered with the drip rate set at maximum. (See Chapter 3 for details on fluid administration.) Horses out in the open should be kept warm with a horse blanket or an aluminum emergency blanket. (See Chapter 8 for details on triage of the trauma patient.)

Sedation
General rules for the use of sedatives cannot be given. What is indicated for one horse may be hazardous to another. The use of sedatives depends on the fracture and, in particular, the type and character of the horse. In most cases, judicious use of a sedative makes the examination and emergency treatment of an acutely traumatized horse much easier, especially when the horse is already stressed from competing in an event or is in pain. Furthermore, horses do not tolerate external coaptation well, especially when the fixation extends above the carpus or tarsus. The use of a sedative may be necessary to induce acceptance of the external coaptation device. Alpha-2 agonists are the drugs of choice, because they have few side effects and provide some analgesia and reliable sedation. Xylazine HCl is suitable for short procedures and detomidine HCl is used for longer sedation. For additional sedation and analgesia, a morphine derivative can be administered as well. Butorphanol tartrate has a wide variety of applications in horses and is an ideal drug for this scenario.

The dosage of these drugs varies according to the type of emergency. Agitated horses usually respond poorly to sedatives and require a higher dosage. In contrast, a lower dosage is needed when the horse’s condition is compromised by shock or severe blood loss. After intravenous injection of the sedative, a minimum of 5 minutes is required for sedation to occur. This time period may seem quite long in an emergency situation, but it is prudent to wait without interfering with the horse to avoid overdosage and an unstable patient. It should be remembered that cold-blooded horses require less sedative on a per weight basis, and the dosage should not exceed that used for a 550-kg horse. Foals usually require heavy sedation to enable good stabilization of a fracture, and it is advantageous to have them restrained in lateral recumbency when a splint is applied.

A combination of detomidine HCl (Dormosedan) and butorphanol tartrate (Torbugesic or Morphasol) is favored by the author. The two drugs can be combined in one syringe and given intravenously or intramuscularly. A 400- to 1000-kg horse should receive 0.5 mL of Dormosedan together with 2.5 mL of Morphasol or 1 mL of Torbugesic (butorphanol tartrate, 0.02 mg/kg), intravenously. Xylazine can be used instead of detomidine; the onset of effects is more rapid but less reliable. The addition of a neuroleptic agent such as acepromazine (0.02 mg/kg) can substantially increase the duration of sedation. However, acepromazine should not be used in stallions or physiologically compromised patients.

Anesthesia
For certain rescue procedures or for the application of a cast, short-term anesthesia may be necessary. Various drug combinations, such as xylazine-diazepam-ketamine or...
xylazine-myolaxin-ketamine, provide reliable anesthesia even in an emergency situation. (See Chapter 20 for more on anesthesia.)

FRACTURE STABILIZATION

Stabilization of the fractured limb in an anatomically normal position is the most important aspect of the initial treatment. This allows the patient to bear some weight without undue damage to the fracture ends and the soft tissues. A very important additional effect of fracture stabilization is the diminution of anxiety and pain for the patient, thereby preventing complications.

Goals of Stabilization

To Reduce Stress and Anxiety and Provide Weightbearing

Pain from instability is extremely stressful for the fracture patient. Effective stabilization of the fracture alone substantially improves the general well-being of the animal. The fractured limb should be stabilized so that the horse is able to bear some weight on it.1 When the pain is reduced, the patient is in better physiological condition for referral and can undergo surgical repair more rapidly. Horses attempt to move the fractured limb constantly in an effort to find a stable position. Therefore, the horse is much quieter once stabilization has been provided (Fig. 78-2).

To Prevent Complications

Horses cannot balance well on three limbs and will repeatedly attempt to use the fractured limb. Continued movement of the fractured bones not only traumatizes the fragment ends, thus preventing anatomic reconstruction of the bone, but also injures the soft tissues, whose integrity is critical for fracture healing. The skin of horses is quite thin, and the worst complication is perforation of the skin by sharp bone fragments, resulting in contamination of the bone ends. Horses with open fractures of long bones have a very poor prognosis, and the use of modern and expensive antibiotics do not change this situation significantly. Thus, all efforts must be made to prevent such a complication. Perforation of the skin occurs quite readily in the distal region of the limb and the medial aspects of the radius and tibia because there is little additional tissue between the bone and the skin.

To Immobilize Adjacent Joints

The joints above and below the fracture must be immobilized, and the stabilization must extend well beyond the fracture line. In no case should the splint end near the fracture line, because it then acts like a lever. A cast should not end at the mid diaphysis, and, when possible, it should include the hoof. For example, splints should not be applied for fractures of the humerus and femur. These requirements sharply limit the number of fractures that can be stabilized with external coaptation techniques.

Types of Stabilization

For emergency stabilization of fractures, robust materials must be used.

Robert Jones Bandage

A Robert Jones bandage consists of many layers of cotton, each held in place and tightened by elastic gauze. Each layer is applied more tightly than the previous one. The finished Robert Jones bandage for a normal-size horse requires 10 to 15 rolls of cotton, and its diameter is about three times the diameter of the limb. This type of bandage can be used for a short period of immobilization. However, it cannot be used to stabilize the limb for long without the addition of splints. When splints are added, the bandage does not have to be as thick.

Splints

A variety of splints are suitable for stabilization of fractures in horses. Splints must be applied to the cranial, caudal, lateral, or medial aspects of the limb and held in place with nonelastic tape. For optimal stabilization, the splints are applied in two planes at right angles (90 degrees) to each other. Sufficient padding and good fixation are necessary to prevent slippage of the splint. The splints can be applied in one or two layers.

Polyvinyl chloride (PVC) splints are very stable and inexpensive but difficult to mold. The commercially available Fraktomedsplint (Fraktomedschiene, Verbandstoff-Fabrik Zürich AG, Fällanden/Zürich), made of a polyvinyl alcohol polymer, is also suitable for immobilization of a fracture but is rarely available in an emergency situation. This type of splint is very rigid when cold and must be heated in steam to facilitate molding it to fit the limb. Within a few minutes, the splint hardens and becomes stable. The Fraktomedsplint is expensive but can be reused many times. Splints can also be improvised using metal rods, broom handles, wooden boards, and other sturdy materials.
materials. The Thomas splint is generally unsuitable for horses and should not be used to splint a fractured limb, especially in an emergency.

**Cast**
The equine cast, also referred to as a synthetic splint, is formed from fiberglass tape impregnated with a polyurethane resin. These materials are very well suited for immobilizing equine limbs. Although it is expensive, it is very strong, cures quickly, is easy to apply, and is very light. While the cast is being applied, the horse should stand quietly to prevent the occurrence of microfractures and folds in the cast, which can reduce its strength and cause pressure sores. This can be helped somewhat if the horse can be supported in a special harness inside an emergency trailer, because there it is usually much quieter. In some situations, this may be difficult, so splints are usually the first choice of stabilization.

**Principles of Stabilization**

**Prevention of Soft Tissue Damage**
Good stabilization does not inflict additional damage to the limb. Swelling of the surrounding tissues is common after an injury and may result in pressure and friction sores as well as tissue strangulation if the splint or cast is not sufficiently padded. The padding should be layered, with each layer being tightened with nonadhesive gauze. Layers that are too thick (2 to 4 cm) allow movement of the bone fragments or slippage of the splint. Ideally, the thickness of each layer of the padding should be about 1 cm.

**Regional Immobilization**
Techniques for immobilization of equine long bone fractures have been established. The limbs can be divided into four distinct regions for stabilization techniques (Fig. 78-3). The regions for the forelimb are (1) the hoof to the distal metacarpus, (2) the distal metacarpus to the distal radius, (3) the distal radius to the elbow joint, and (4) the elbow joint to the distal scapula. The regions for the hindlimb are (1) the hoof to the distal metatarsus, (2) the distal metatarsus to the tarsus, (3) the tarsus to the stifle joint, and (4) proximal to the stifle joint.

**Specific Applications**

**Fractures of the Proximal, Middle, and Distal Phalanges, and the Distal Sesamoid Bone**
Incomplete and complete fractures of the proximal, middle, and distal phalanx and the distal sesamoid bone are easily stabilized with either a cast or a splint. With fractures of the proximal or middle phalanx, the third metacarpus and third metatarsus (MCIII/MTIII) and the proximal and middle phalanx must be stabilized in an almost straight line to prevent movement in the frontal plane at the fracture line. To achieve this, the heels are raised with a wedge, which also serves to facilitate the attachment of the cast distally. With the limb in this position, a cast is applied from the heels to the proximal end of the MCIII/MTIII. To obtain optimal stabilization, the entire hoof, or at least the heels, should be included in the cast. If nonmoldable splints are used instead of a cast, they are preferably fixed dorsally (see Fig. 78-4).

Holding the forelimb off the ground makes application of the synthetic splint easier because the horse is less likely to move. However, this is not possible with the hindlimb because of the reciprocal apparatus, which causes flexion of all the joints when the limb is held off the ground. However, with proper sedation, most horses will stand quietly for a few minutes with the injured limb lightly touching the ground and in a fairly normal position. Various other splints such as the Kimzey (Fig. 78-4) or monkey splint (Fig. 78-5) can be used instead of a cast.

**Figure 78-3.** A, Biomechanically important divisions of the forelimb from distal to proximal: (1) distal to the distal quarter of MCIII, (2) from the distal MCIII to the distal radius, (3) from the distal radius to the elbow joint, and (4) from the elbow joint to distal scapula. B, Biomechanically important divisions of the hindlimb from distal to proximal: (1) distal to the distal quarter of MTIII, (2) from the distal MTIII to the tarsus, (3) from the tarsus to the stifle joint, and (4) proximal to the stifle joint. (From Bramlage LR: Com Cont Educ Pract Vet 1983;5:S564.)

**Figure 78-4.** A Kimzey splint applied to the distal limb of a horse. These splints are well suited for first aid for disruptions of the suspensory apparatus.
Fractures of the Third Metacarpal, Third Metatarsal, Carpal, and Tarsal Bones

With fractures of the MCIII/MTIII, a cast or splint is applied from the hoof to the elbow or stifl joint, respectively (Figs. 78-6 through 78-8). Depending on the temperament of the horse and the location of the fracture, the splint or cast may reach only the top of the calcaneus for fractures of the metatarsus. However, this does not produce optimal stabilization and should be looked at as an exception rather than the rule. Extending the external coaptation above the tarsus should always be the goal and should in most cases be possible with the use of adequate sedation.

Figure 78-6. Application of a full forelimb splint. The padding is applied evenly in several layers over the entire limb, and each layer is tightened separately. A PVC-pipe splint is applied to the caudal aspect of the bandage and augmented with one pole medially and laterally. The splints are incorporated into the bandage with tape.

Figure 78-7. Application of a full forelimb cast using the technique described in Figure 18-17 but extending over the entire forelimb up to the elbow joint. Care is taken to apply the cast material evenly along the entire limb and to fold back the stockinette over the top of the cast, incorporating it into the last layer to provide a smooth top edge.

Figure 78-8. A horse with a fracture of the metacarpus, which has been stabilized with a full limb cast. The horse is loaded in an emergency trailer and is ready for the transport. The harness supports the patient during the transport.
Fractures of the Radius and Tibia
Fractures of the radius and tibia present special difficulties because the large muscle masses prevent fixation of the elbow and stifle joints. Furthermore, contraction of the extensor tendons, located cranio-laterally on the limb, causes abduction of the limb below the fracture line, which can produce skin perforation on the medial aspect of the radius or tibia (Fig. 78-9, A and B). Therefore, stabilization up to the elbow or stifle is not sufficient and will not prevent abduction. In these fractures, a stable splint or cast should first be applied up to the elbow or stifle joint (see Fig. 78-9, C). This should then be augmented with an additional splint applied laterally and reaching from the hoof to the point of the shoulder or hip, respectively. Additional padding is added to the splint so that it conforms to the contour of the limb. Immobilization is difficult in the hindlimb because of the reciprocal apparatus (see Fig. 18-15). Flexion of the stifle, which cannot be prevented, results in flexion of the hock via the superficial digital flexor muscle and the peroneus tertius muscle. This results in large forces acting on the tibia so that dislocation of the fragments is unavoidable. Regardless, these fractures are stabilized as well as possible using this technique.

Fractures of the Ulna
Fractures of the ulna result in failure of the passive stay apparatus of the forelimb (triceps apparatus), which allows the horse to stand with little muscular effort for prolonged periods of time. Therefore, the limb should be stabilized with a splint that extends the carpus so that the horse can bear weight on the limb. The splint should be applied caudally and should extend from the metacarpophalangeal region to the level of the elbow joint (Fig. 78-10).

Figure 78-9. Splinting of a proximal radial fracture. A, All the muscles are arranged cranially, laterally, and caudally, which results in a lateral deviation of the limb when the muscles contract to provide support to the fractured limb. This may result in perforation of the skin at the medial aspect of the radius or tibia by sharp bone edges. B, A Robert Jones dressing or cast has been applied to the limb. It ends near the fracture site and provides only limited support. Also, it increases the leverage arm, causing more tissue damage. C, The incorporation of long splint or wooden plank to the lateral aspect of the bandage effectively counteracts the valgus-inducing forces and adds significant stability to the splint bandage. With such a splint, the patient may load the fractured limb.

Figure 78-10. A, Typical posture of a horse with a fracture of the olecranon process of the ulna. B, The carpus cannot be maintained in a straight position because the triceps muscle pulls on only the proximal fragment, which results in the formation of a fracture gap (arrow).
Fractures of the Humerus and Femur

Fractures of the humerus and femur do not require a bandage or a splint because they cannot be adequately immobilized and there is enough muscle mass to protect the bone. These fractures are rarely open and a bandage would be counterproductive, because it would only add weight without providing stabilization. In some cases, fractures of the humerus or neck of the scapula can be helped with a splint that extends the carpus, similar to the situation with fractures of the ulna.

TRANSPORTATION OF THE HORSE

The injured horse must be transported carefully and humanely, according to animal welfare legislation. It is advantageous to have a specialized large-animal trailer or van and the support of an experienced veterinarian or assistant. However, some controversy exists: there are those who think that this kind of transportation can be accomplished with normal horse trailers that are slightly adapted. In the experience of the authors, horses with a fracture should be transported by a specialized large-animal trailer built for the transportation of injured horses.

Equipment

The emergency trailer or van should have enough room for two standing horses (Fig. 78-11, A) or one recumbent horse. Ideally, there should be enough space to handle the horse from all sides. The trailer should be approximately 30 cm higher than standard horse vans, and it should be equipped with a nonslip floor (see Fig. 78-11, B). It should be well ventilated and spacious with a good lighting system for night transport. Additionally, the vehicle should be solidly built, preferably of aluminum. The loading and unloading ramps should be long enough that the slope is minimal, which is especially important for horses wearing a splint. The ramp must have an even nonslip surface, and the end must be flush with the ground. The vehicle must be equipped with a winch and a strong frame to support a harness. Different sizes of suspensory harnesses are required with a minimum carrying weight of 1200 kg. Other requirements are a gurney or a mat on which a recumbent animal can be pulled into the trailer. Curtains or movable, lightweight walls are helpful when the working area needs to be blocked off from the view of spectators. For safety reasons, the driver must be able to observe what is going on via a video camera and able to have audio contact with the support assistants caring for the horse during the transport. The vehicle should be equipped with a heater and the floor should be well padded (e.g., with an air mattress) to minimize vibrations during the transport of a recumbent animal. The interior installations should be adjustable to accommodate horses of different breeds and sizes. The emergency trailer or van should be stocked with all the necessary medical supplies for various emergency treatments including shock therapy.

Loading Injured Horses

It is best to maneuver the vehicle as close to the injured horse as possible to spare it unnecessary walking. As the steepness of the loading ramp increases, so must the interior height of the trailer (minimum height, 2.35 to 2.50 m), particularly when a forelimb is injured. Increasing the height of the trailer jack will lower the height of the ramp.

Figure 78-11. Ideal emergency vehicle. A, The SUV is equipped with blinking lights and all the necessary emergency equipment for rescuing horses. Additional equipment is stored on the side of the trailer. B, The trailer has an axle constructed close to the ground, which results in a ramp with a gentle slope. This ramp angle makes loading a patient wearing a splint easy. The roof is reinforced to allow the installation of a support harness. A winch is built into the front wall to allow a recumbent patient to be pulled into the trailer.
somewhat. Horses also load better when the trailer is positioned so that the horse can walk in the same direction as the barn. The horse should be acclimated to the cast or splint by walking a few steps before being loaded.

Application of a bridle over a halter is recommend for better control during loading. In this way, fractious horses can be better controlled by a handler walking on the side. Two readily available lunge lines are tied to either side of the trailer and are used to direct the horse into the vehicle. For injured horses, the stall partition should be moved to one side to provide the maximal amount of space for loading. Before loading, the service door and the front-unloading door should be opened and the interior lights turned on at night to illuminate the interior as much as possible. Two assistants hold the lunge lines and move slowly toward each other, progressively narrowing the space between them. Touching the horse with the lines may help loading and is not necessarily discouraged. As soon as the horse is in the trailer, the ramp bar is replaced, the ramp is closed, and the service door and the front-unloading door are closed. The stall partition and chest bar are the last barriers to be put in place.

It has been recommended that horses with forelimb fractures be transported facing backward in an attempt to relieve the stress on the forelimbs during braking. However, almost all standard European two-horse transporters do not provide enough space for the horse to comfortably stand backward; when the chest and rump bars are in place, the horse would have to keep its head either very high or turned to the side because of the ramp (the back door) in front of it. This would be very uncomfortable for the horse. Furthermore, the head and neck are important for balance but they have to be free to perform this function properly. Finally, it is very difficult if not impossible to load an injured horse backward or to turn it around once it is inside the trailer. Loading the horse via the front unloading ramp is not practical because the space is limited and the slope of the front ramp is usually steeper than that of the rear ramp. For a horse standing backward in the trailer, the injured forelimb would then be positioned at the back of the transporter between the rear axle and the ramp, where the ride is the roughest.

The horse has to balance not only during braking but also during acceleration and in curves. Therefore, the driver must take the time to ensure a comfortable ride for the horse. A video camera in the trailer is very helpful. An assistant in the trailer with the horse helps to calm it and relay any developing problems directly to the driver. For horses with hindlimb injuries, the driving speed must be as slow as possible, because the ride is the roughest behind the rear axle.

**Transport in a Supporting Harness**

A harness should be used to transport horses with severe injuries. Many horses allow the harness to support their entire weight during transport. Most horses alternately rest one limb and then the other. After some time, horses with a properly splinted limb frequently bear some weight on the fractured limb while being supported by a harness, thereby resting the healthy contralateral limb. Transportation in a harness can provide tremendous relief for an injured horse. For this type of transport, a person experienced in large animal rescue operations should always be present in the trailer to provide optimal care for the patient. In extreme cases, a veterinarian may be required to travel with the horse as well. The harness must be fitted so that it does not interfere with the horse’s respiration and balance. It allows the horse to rest its limbs during transport, which reduces anxiety and pain and improves the general attitude of the patient. Horses that are transported with a harness arrive at the hospital in much better general condition than those that are not. Most horses can be easily positioned in a harness provided that it is applied snugly and gives support to the patient from the front as well as from the back. During transportation, the bellyband is tightened several times, and the front and hind belts are adjusted until the horse is comfortable. It is imperative that everything be checked repeatedly throughout the transport, so that problems can immediately be identified and corrected (Fig. 78-12).

**Unloading Fracture Patients**

In general, the horse should get off the trailer using the sound limbs first. With a forelimb injury, the horse should be backed off the transporter. With hindlimb injuries, the horse should be unloaded via the front ramp. As for loading,
the trailer jack can be adjusted to provide the optimal ramp angle for unloading.

Injured horses, particularly those with fractures, should be lightly sedated for unloading. Most horses feel insecure when they are presented with new surroundings and when forced to use the injured limb after having been supported in a harness. This stress may result in hectic or hesitant and uncontrolled movements during unloading. Sedation dampens these reactions, and unloading is safer for both the horse and the handlers.

**Transport of Recumbent Horses**

It is a general rule that horses should be transported standing whenever possible. Horses that are unable to stand are transported in lateral recumbency, and anesthesia may be induced for the ride to the clinic.7 Transportation of horses under general anesthesia is rare; the anesthesia must be carried out and maintained by a veterinarian, who must travel with the horse. The duration of transportation in such cases must be as rapid as possible, perhaps assisted by a police escort, and it should not exceed 90 minutes.

A mechanical or electric winch, transport mat, insulated air mattress, head protection for the horse, and hobbles are some of the equipment needed for transportation of recumbent horses.

Once the decision has been made that the horse is to be transported in recumbency, an indwelling intravenous catheter is placed and intravenous fluids are started. This is the only way of ensuring rapid treatment at any time. Horses that cannot rise are sedated and those that can rise are anesthetized so they can be transported in recumbency. After induction, anesthesia must be maintained during the entire transport period. General anesthesia is usually induced and maintained using injectable drugs, some of which can be administered via a drip (see Chapter 20). The van is positioned as close to the horse as possible, and the stall partition is placed to one side so that the entire interior space can be used. The winch wire is pulled out to the desired length and the horse is placed on the rubber transport mat or another device so that it can be pulled into the van. Either a hand or electric winch can be used, but there should be a backup if the electric one fails.

For recumbent horses, leather boots are placed on the hooves to reduce the risk of injury, and hobbles are put on all limbs. The head and especially the eyes must be well protected. This is best achieved with padded leather headgear, after the halter has been removed to prevent damage to the facial nerves. The horse can be pulled into the van using a slide mat.

Recently, special air mattresses have been developed for the transport of recumbent horses; these mattresses are used by the large-animal rescue unit operating in Switzerland and Liechtenstein (Herr Ruedi Keller, Embrach).8 Before inflation, the air mattress is placed between the horse and the transport mat, which are then pulled into the van together. The mattress is then inflated using compressed air. This procedure takes about 2 minutes and ensures a comfortable ride for the patient. Horses can be transported great distances without the risk of pressure necrosis or nerve damage (Fig. 78-13). Often, the amount of drugs used to sedate the horse can be reduced as well.

The journey should begin as soon as the horse is in the van, because transportation time is critical. In special circumstances, a police escort should be arranged. A veterinarian or veterinary assistant should accompany the horse so that sedation or anesthesia can be maintained. An audio-video system helps to ensure the safety of the personnel accompanying the horse. For long distances, a mobile anesthetic machine operated by experienced assistants may be necessary. This enables the administration of intravenous fluids and air supplemented with oxygen (approximately 2 to 12 L of oxygen per minute). Unloading the recumbent horse is straightforward and is achieved by pulling the transport mat out of the van with a winch or crane or by hand.

MOLECULAR BIOLOGY TECHNIQUES

CHAPTER 79

Molecular Biology Techniques in Musculoskeletal Research
Brigitte von Rechenberg
Michael O. Hottiger

BACKGROUND

Molecular biology is the branch of science devoted to studies of the structure, function, and reactions of DNA, RNA, proteins, and other molecules in connection with life processes. In 1953, Watson and Crick were the first to determine the true crystalline structure of deoxyribonucleic acid. DNA is the elementary template carrying the essential genetic code for every living organism. In the eukaryotic cells that make up plants, animals, and other multicellular organisms, most of the DNA is found in the chromosomes, which are located in the cell nucleus. Once the structure of DNA was identified, the mechanisms behind heredity, information flow, and gene function fell into place. In 1958, Crick described the paradigm of molecular biology in which the flow of information is depicted as DNA → RNA → protein. DNA is replicated (i.e., DNA is synthesized from DNA), whereas RNA is transcribed from DNA. It is called transcription because the same type of "language" is used in DNA as in RNA—that is, nucleic acids. In some cases, RNA may be used to make complementary DNA (cDNA) (i.e., reverse transcription) using a particular enzyme called reverse transcriptase. Protein is synthesized from messenger RNA (mRNA) by translation. This is called translation because a different language is used—that is, amino acids instead of nucleic acids. Once protein has been synthesized from RNA, the information is trapped. In other words, there is no known mechanism that allows information to flow back into RNA from protein.

Thousands of genes are being discovered for the first time by sequencing the genomes of model organisms, a reminder that much of the natural world remains to be explored at the molecular level. With the recent completion of the sequencing of the different genomes, it appears that now a map of a defined being exists. In a genetic map, the location of the genes is assigned to the different chromosomes. A gene is the functional and physical unit of heredity passed from parent to offspring. Most genes contain the information to synthesize a specific protein. However, it is the proteins of those genes that interact with each other in the context of a cell (or more appropriately, in the context of a whole organism, unicellular or multicellular). In eukaryotes, certain proteins are targeted to particular compartments within the cell (e.g., organelles such as mitochondria, endoplasmic reticulum). Where a particular protein will go can be predicted by the signal sequence that is encoded by the gene. However, a genetic map by itself cannot describe how proteins will interact with one another.

Genomics refers to the study of genes and genomes, whereas proteomics is the study of proteins (i.e., protein structure and function, and their interactions in an organism). Now that several genomes have been sequenced, research focuses on protein structures and interactions (primarily for the purpose of medically relevant information).

Molecular techniques alone, however, are not sufficient to explain complex cell mechanisms, which always warrant a combination of biochemistry, chemistry, and other life science fields such as cell biology. Molecular techniques used for applications in cartilage resurfacing or bone augmentation and enhancement usually involve scientists who provide basic scaffolds or carriers for tissue engineering and engineers who construct the necessary bioreactors where tissues are grown in vitro. Molecular techniques have led to explanations of how biomechanical forces (e.g., compression, strain, tension) induce signaling pathways on a cellular level in fibrous tissue, cartilage, bone, and tendons. Almost 110 years after Wolff wrought "the law of transformation of bone according to mechanical load," molecular biology provided the foundation to understand what causes this transformation on a molecular level.

The introduction of molecular biology into the field of musculoskeletal research has opened new avenues for understanding the pathophysiology of musculoskeletal structures, including bone, cartilage, tendons, periosteum, paratenon, and perimysium. Through molecular techniques, signal pathways and signal molecules involved in synthesis and degradation of matrix macromolecules can be identified and manipulated for diagnostic and therapeutic purposes. For example, once the pathway of pathologic articular cartilage degradation is better understood, the use of molecular techniques aimed at downregulating DNA/RNA expression of degradative protein concentrations and the use of knockout or transgenic mice to upregulate protective mechanisms, will be possible. Furthermore,
The osseous structures of the tibial region include the tibia and fibula. The fibula is a rudimentary bone of variable shape and completeness. In most cases the fibula is incomplete and consists of several centers of ossification that are often mistaken for fibular fractures. Rarely, an atavistic complete fibula is identified radiographically in a pony or miniature horse foal.

The pathology associated with this condition creates limb deformities and tarsal arthritis (see Chapter 89). Other than traumatic injury, this is the only condition in which lameness is associated with the fibula.

By far the most common injuries of the tibial region are fractures. There are two common types of fractures of the tibia in the horse: the proximal physeal fracture and the diaphyseal fracture. The latter can be complete with displacement and instability, or it can be incomplete and stable.

PROXIMAL PHYSEAL FRACTURES

The most common tibial fracture in foals is the Salter-Harris type II proximal physeal fracture of the tibia (Fig. 100-1). It most often occurs when the foal is kicked from the lateral aspect on a weight-bearing rear limb. The soft tissue of the medial proximal tibial physis ruptures because of the tension created on the medial side of the limb when the traumatic bending force is applied. The fracture propagates across the tibial physis from medial to lateral approximately two thirds the width of the bone, at which point the medial bending force on the distal limb distracts the physis, changing the fracture plane orientation to vertical, leaving the lateral physis intact and a triangular metaphyseal fragment attached to the epiphysis.

With this fracture, the periosteal soft tissue is normally intact laterally but disrupted on the medial aspect. Occasionally, complete disruption of the soft tissue surrounding the physis occurs, rendering the fracture more unstable and creating more displacement.

Preoperative Considerations

The biomechanical force that creates the fracture is a tension force medially; therefore, fracture instability is best neutralized by re-establishing support on the medial aspect of the limb. This requires an implant that maintains the proximal tibial physis in a stable position on the metaphysis. Because normal bone formation, as part of bone growth, is already active in the growing physis, development of the vascular support system for fracture healing is unnecessary. Therefore, the fracture heals rapidly if it is stable, normally in 3 to 4 weeks (see Fig. 100-1).

Screw fixation, pinning, and external fixation have been described for treating this fracture, and plate fixation has been used on the lateral aspect of the tibia. A biomechanically stable fixation re-establishes the tension support on the medial aspect of the limb, a function that was previously provided by the soft tissue of the physis. If the lateral soft tissue is intact, stability is relatively easy to obtain. If the epiphysis is completely disrupted from the metaphysis, more elaborate fixation with more implants is required.

Although this fracture is usually closed, soft tissue damage occurs medially at the site where implants must be inserted. The close implant-to-skin location makes sepsis more difficult to avoid. Broad-spectrum antimicrobial agents and anti-inflammatory medications are administered preoperatively.
Treatment

The treatment of choice for proximal physeal fractures of the tibia in foals is medial plate fixation. The foal is positioned in either dorsal or lateral recumbency. When it is placed in lateral recumbency with the injured limb down, pressure on the proximal tibial physis facilitates reduction. The opposite rear limb is flexed, abducted, and tied vertically to prevent it from interfering with surgery on the medial aspect of the injured limb.

The approach to the proximal aspect of the tibia for medial plate application is along the caudal margin of the tibia. The soft tissue is elevated cranially, and the plate is placed on the medial aspect of the tibia. The close apposition of the tibia to the surface of the skin with no interposed muscle on the medial aspect of the limb complicates wound healing if the skin incision lies directly over the implant. Therefore, a slightly curved incision is initiated distally on the caudomedial aspect of the limb and extended craniodorsally along the surface of the proximal tibia. The proximal tibial physis is thin, and screws must be inserted sufficiently proximal to the growth plate to allow purchase in the bone but without endangering the articular surface. Placement of long needles along the plane of the proximal tibial physis permits orientation of the plane of the physis during drilling for screw placement.

Gentle traction on the physis separates the fracture plane and allows careful débridement. Removal of small fragments and blood clots permits accurate reduction of the physis. Damage to the growth cartilage of the physis is normally induced by the metaphysis near where the fracture plane changes from transverse to vertical. Evaluation of the physal cartilage provides information on the likelihood of survival of proximal tibial growth plate function. The amount of damage depends on the time from injury to surgery and the adequacy of preoperative immobilization.

After the debris is removed from the fracture, the soft tissue must be elevated along the medial aspect of the proximal tibial physis. If this soft tissue is not elevated, it becomes trapped between the metaphyseal fragment and the physis, preventing complete reduction. Manual downward pressure on the medial aspect of the proximal tibial metaphysis places the intact soft tissue on the lateral aspect of the limb under tension and reduces the fracture. Reduction is maintained by the cranial placement of one 4.5-mm cortex screw in the epiphysis and one in the metaphysis. A figure-eight tension band wire is tightened between the two screws, maintaining reduction during placement of the primary implants.

Soft tissue dissection is carried to the bone surface on the metaphysis, but the soft tissue on the epiphysis should not be disturbed. A four-hole T-plate, right angle plate, or five-hole broad limited-contact dynamic compression plate (LC-DCP) or dynamic compression plate (DCP; see Fig. 100-1) is used for fixation. (T-plates and right-angle plates are named according to the number of vertical holes in the shaft; for example, a four-hole T-plate contains two horizontal holes and four additional holes in the vertical shaft.) The two transverse holes are positioned in the epiphysis closer to the posterior aspect of the proximal tibia, halfway between the stifle joint surface and the physis. The two proximal screws are inserted across the entire width of the epiphysis using needles in the physis for orientation. The use of 5.5-mm screws is ideal in the epiphysis. The four distal screws in the T-plate are inserted into the metaphysis after using the tension device or are placed in the load position to achieve compression. A second screw and wire insertion can be used to increase stability if needed (see Fig. 100-1).

Once fixation is complete, the soft tissue is closed. Closed suction drainage is optional. A stent bandage is sutured over the incision to reduce tension on and protect the incision. The area is difficult to bandage, but some compression of the soft tissue to reduce the hematoma can be obtained if elastic tape is used.

Aftercare

External coaptation is not used. The foal is assisted to its feet during recovery from anesthesia. Broad-spectrum antibiotic therapy along with anti-inflammatory treatment is continued until the swelling has subsided. The condition of the soft tissues postoperatively determines the length of antibiotic treatment. Foals are confined to the stall for 4 weeks, after which time radiographs are taken. If there is any indication of postoperative complications, radiographs are taken earlier. The foal should be bearing weight on the limb within 1 or 2 days and should begin walking soundly within 7 to 10 days. Absence of soundness indicates developing complications.

Complications

Three major complications are commonly encountered with this fracture: failure of the fixation, sepsis, and wound dehiscence. Failure of the fixation most commonly occurs by loss of purchase within the epiphysis. Failure seldom occurs from implant loosening in the metaphysis (Fig. 100-2) or by disruption of the implants themselves. Postoperative sepsis is possible, as with any equine fracture. A third complication that indirectly results in sepsis is dehiscence of the wound. The skin and subcutaneous tissue on the medial aspect of the limb are often traumatized by the sharp edge of the proximal tibial metaphysis if the duration from fracture to treatment was prolonged or if postinjury first aid was not adequate. Sepsis does not necessarily mean failure as long as it is appropriately treated with drainage and antibiotics sufficient to allow healing to occur and as long as stability is maintained.

Prognosis

The prognosis after repair of proximal physeal fractures is favorable, but the smaller the foal, the better the prognosis.13

The preoperative condition of the soft tissues, the amount of soft tissue stability on the lateral aspect of the limb, the ability to reduce the fracture, and the security of the proximal epiphyseal implants all determine the outcome. Sufficient healing of the fracture and resolution of the injury to allow athletic activity are anticipated in 50% of cases. Closure of the proximal tibial physis occasionally occurs, but it is not a major complication. The proximal tibial physis of the horse does not close as readily as the physis of other animals or other sites, and the horse compensates for decreased limb length in spite of considerable damage if closure does occur.
DIAPHYSEAL FRACTURES

Diaphyseal fractures are the second common type of fracture of the tibia. Most diaphyseal fractures have a spiral configuration and are comminuted (Figs. 100-3 and 100-4). The fracture is created when the forces of loading, which in the tibia create considerable torque, are combined with an excessive external force. Diaphyseal fractures can occur in animals of any age. Appropriate first-aid therapy is necessary to minimize secondary soft tissue damage, as with any fracture (see Chapter 78). The trauma required to fracture a tibia often creates an open fracture.

Incomplete Fractures

Horses with incomplete fissure or stress fractures of the tibia have marked lameness that often resolves quickly. Pain can be elicited with palpation, but the diagnosis is made radiographically or with nuclear scintigraphy. It is important to include several oblique projections at different angles to identify the faint fracture planes. Occasionally, no fissure is seen at the initial examination. This is an indication for nuclear scintigraphy.

A stress fracture is suspected and the animal is placed in a stall. The radiographic examination is repeated 8 to 14 days later, at which time the fracture is usually identified. Stall rest is continued until the horse is sound. Initially, in tractable horses, it is prudent to prevent the horse from lying down either by tying it in front of a hay net or by applying a rescue net (see Fig. 81-1) This judgment must take into consideration the demeanor of the horse, because the risk of displacement might be increased in some horses because of restriction of movement.

Healing is monitored through monthly radiographs. Once healing has progressed adequately (usually in 3 to 4 months), a slowly increasing exercise program is begun. The prognosis for nondisplaced tibial fractures is favorable if they do not displace. The horse can resume work 30 days after the fracture is healed.
Complete Fractures

Preoperative Considerations

Usually, diaphyseal fractures of the adult tibia are high-energy, catastrophic injuries accompanied by extensive comminution and are quite often open. For these reasons, attempts at repair are seldom made. However, this fracture in foals usually has less comminution and repair has a greater chance of success.

Traction on the distal limb does not reduce a tibial fracture; in fact, it causes overriding because of the reciprocal apparatus. Placing the injured tibia down with the horse in lateral recumbency impedes surgical manipulation of the diaphyseal fracture and necessitates a medial surgical approach, where little soft tissue covers the bone and implant. Therefore, the horse is best positioned in dorsal recumbency or in lateral recumbency with the injured tibia uppermost.

Approaches to the tibia for diaphyseal fracture repair must take the following anatomy into consideration. The cranial tibial artery is located on the cranial lateral aspect of the tibia. The lateral outpouching (sulcus muscularis) of the lateral femorotibial joint compartment extends distally, surrounding the long digital extensor tendon on the proximal lateral aspect of the tibia. The tenuous soft tissue on the medial aspect of the tibia and the closely attached digital extensor tendons distally must be avoided near the tarsocrural joint.

Three surgical approaches are available: the medial approach directly over the tibia without muscle cover; the lateral approach between the long digital extensor and the cranial tibial muscles; and the cranial approach, in which the incision is made over the cranial tibial muscle. The cranial approach over the muscle is the most versatile.

Deep dissection is extended slightly medially and the periosteum is incised, allowing the muscle and periosteum to be retracted as one unit laterally, permitting a cranial approach to the proximal tibial shaft. The cranial approach eliminates the necessity of dealing with any blood vessels, because all the vasculature is elevated with the periosteum and the cranial tibial muscle. Implants can be placed on the medial and lateral aspects of the bone through this incision, eliminating the need for two incisions, as with the medial and lateral approaches. The biomechanics of weightbearing of the tibia dictate that two plates be used, that one plate be placed craniolaterally to neutralize torque loading, and that the major implant be placed on this tension surface of the bone (see Figs. 100-3 and 100-4).

Broad-spectrum antimicrobial agents and anti-inflammatory medications are administered preoperatively.

Figure 100-3. A and B, Cranio-caudal and lateromedial radiographs of a mid-shaft tibial fracture in a foal. The fracture was repaired with three cortex screws applied across the fracture in lag fashion. Additionally, a long plate, spanning the tibia from one metaphysis to the other, and a shorter second plate at 90 degrees to the first was implanted. C and D, Cranio-caudal and lateromedial radiographs of the repaired fracture when the foal was discharged from the hospital. E and F, Cranio-caudal and lateromedial radiographs of the healed fracture—after the plates were removed 5 months after the fracture. The three initial screws were covered by bone and, therefore, were left in place.
Treatment

The incision is initiated craniolaterally along the lateral patellar ligament, extended to the tibial crest, directed cranial over the cranial tibial muscle to the distal aspect of the limb, and curved slightly medially as the tarsocrural joint is approached. The incision is carried through the skin and subcutaneous fascia until the cranial tibial muscle is encountered. The cranial tibial muscle is elevated laterally, the periosteum is incised, and a subperiosteal dissection plane is established from cranial to lateral, exposing the lateral surface of the bone.

Positioning of the implant at the most proximal aspect of the tibia in proximal metaphyseal and mid-diaphyseal fractures necessitates entering the stifle joint through the sulcus muscularis, which surrounds the long digital extensor muscle. Normally, the long digital extensor and cranial tibial attachments are avoided by separating them, which allows placement of the implant near the proximal physis or phyleal scar. Working on both sides of the cranial tibial muscle allows placement of the plate without damaging the muscle.

Fracture reduction is accomplished by traction on the distal tibia and appropriate reconstruction of the bone. The repair begins by reattaching comminuted fragments to the parent bone with lag screws to create a two-fragment fracture. The fracture is reduced to a proximal and distal fragment, and the plate is contoured to mimic the curve of the tibia from craniolateral proximally to cranial distally (see Figs. 100-3 and 100-4). The use of dynamic condylar screw (DCS) plates or 5.5-mm LC-DCPs is strongly encouraged, especially in older foals and the rare adult horse subjected to treatment. The screws are inserted in the order dictated by the individual fracture, which differs from case to case. Care must be taken to cross each fracture plane with screws placed in lag fashion and to create interfragmentary as well as axial compression during application of the plate for the most stable fixation.

Once the craniolateral plate is in place, the craniomedial plate is applied. It is contoured from proximomedial to medial and positioned in an envelope under the skin and subcutaneous tissue created by elevation of the periosteum medially. It is occasionally necessary to flex and abduct the limb to gain access to the medial aspect of the tibia. The medial plate is positioned to avoid the screws of the lateral plate. Interfragmentary and axial compression is created as needed. Both plates can be loaded to distribute the axial compression circumferentially around the bone. Plate luting has been advocated for repair of this fracture to increase stability and fatigue life of the implant construct. After placement of the plates, a suction drain is inserted, exiting proximolaterally, and attached to a suction reservoir.

Closure involves the fascia of the cranial tibial muscle, subcutaneous tissue, and skin. Release incisions can be made in the skin over the cranial tibial muscle to relieve tension on the closure if perioperative swelling and operative manipulation have increased the diameter of the limb.

Postoperatively, no cast is used. Cast immobilization increases the load on the implants because the cast cannot extend proximal to the stifle in the horse and the stifle joint cannot be immobilized. Stent bandages are sewn over the incision. The horse is allowed to recover from anesthesia unimpeded by bandages; bandages are placed once the horse is standing. The horse is always assisted in recovery; it should be helped to regain the standing position in one attempt, if possible. Bandaging is used as indicated during the postoperative period.

Aftercare

Antibiotics and anti-inflammatory drugs are continued for a prolonged period because tibial fractures are accompanied by considerable soft tissue damage. The health of the soft tissue and the postoperative use of the limb by the patient dictate the length of antibiotic and anti-inflammatory therapy.
Stall rest is maintained, with no exercise allowed for 6 to 8 weeks, depending on the age of the horse. Foals are often radiographed at 6 weeks, whereas follow-up radiographs are taken at 8 weeks in adults to ascertain whether bridging of the fracture has occurred. Postoperative use of the limb is the most accurate assessment of stability of the fracture. If use of the limb is not attained or diminishes, radiographs are taken.

**Complications**

The most common complication with tibial fractures is breakdown of the fixation because of bone or implant failure. Tibial fractures are most often comminuted in configuration, and the torsional force applied to a fractured bone that contains multiple drill holes often causes propagation of the fracture into additional sites. A single acute overload generally causes the bone to fail. Complications also include postoperative sepsis because of primary infection or breakdown of the incision. With any major long bone fracture, failure of the implants can occur with repeated cyclic loading.

**Prognosis**

Simple fractures in adult horses can be repaired successfully with internal fixation (see Fig. 100-4); however, this fracture configuration is the exception rather than the rule. Most diaphyseal tibial fractures are comminuted and accompanied by massive soft tissue damage. Therefore, the prognosis for tibial fractures is unfavorable in adults. In foals, however, internal fixation of tibial fractures can be successful when the fracture is immobilized and the implants protect the bone enough to allow healing' (see Fig. 100-3). The prognosis is guarded even in foals, but 60% success in healing of the fracture and dismissal of the horse post-operatively is attainable in selected fractures. Athletic activity is undertaken if the surgical procedure and stabilization proceed without complications.

**DISTAL PHYSEAL FRACTURES**

Fractures of the distal epiphysis occur rarely. Diagnosis is routine, and treatment involves external coaptation with a fiberglass cast alone or in conjunction with selective screw placement. The architecture of the undulating articular surface of the distal tibia and the corresponding physsis makes implant placement into the epiphysis especially difficult, because neither should be endangered.

**TIBIAL CREST FRACTURES**

Tibial crest fractures are generally the result of direct trauma, often during attempts to jump a fence or from contact with other solid objects. By far the most common type of tibial crest fracture is the non-displaced non-articular fracture (Fig. 100-5). These fractures require no fixation because the patellar ligaments provide adequate stability for healing. Stall confinement for 60 days with follow-up radiographs at that time usually show adequate healing for gradual re-introduction to exercise.

If the tibial crest fracture is displaced or is articular (Fig. 100-6), the fracture is stabilized in much the same fashion as a proximal tibial physeal fracture with fixation and stabilization employing a tension band cranially and implants sufficient to stabilize the fracture and reconstruct the joint surface.

![Figure 100-5.](image) Lateromedial radiograph of the most commonly encountered tibial crest fracture. It usually results from impact of the hindlimb on a solid object such as a fence post or rail. If it is not displaced, it requires no fixation.
REFERENCES

Figure 100-6. A, Lateromedial radiograph of a displaced tibial crest fracture. B, The fracture was repaired proximally with two 5.5-mm cortex screws applied in lag fashion perpendicularly across the fracture plane. In one screw, a washer was applied to avoid countersinking and concomitant weakening of the bone. Additionally a five-hole narrow dynamic compression plate (DCP) was applied over the medial ridge as a tension band and a five-hole 2.7-mm cuttable small animal plate with two 3.5-mm cortex screws over the lateral aspect of the fracture to provide a greater area of fixation and reduce stress concentration. The fracture healed without complications.
CHAPTER 101

Stifle
John A. Stick

Because the stifle is the most complex and largest joint in the horse, it represents an important cause of hindlimb lameness.1 Although it is cited as a common location of hindlimb lameness in the horse, the incidence is reported to be between 2% and 8% of all musculoskeletal problems that occur in lameness surveys.2,3

Stifle lameness clinically appears as swelling in the stifle region and is referred to as gonitis. The injury can be to soft tissue, bone, or cartilage, and it can range from simple sprains with a favorable prognosis to severely debilitating lameness necessitating humane destruction. With long-standing stifle involvement, atrophy of the gluteal muscles on the affected side may be apparent, and wearing of the toe of the affected hindlimb is common. The degree of lameness varies from almost occult to nonweightbearing, and when viewed from the rear, asymmetry of the gait is similar to hindlimb lameness seen from other causes.

Although minor injuries are generally accepted to originate in the soft tissue, bone involvement has been cited to have a higher incidence than soft tissue injury in one case study.4 Uncertainty surrounding the diagnosis of conditions affecting the stifle joint in the horse 10 years ago have given way to accurate definitive descriptions of numerous disorders. With the advent of digital capture radiography techniques, fluoroscopy, scintigraphy, new applications of ultrasonography, and computed tomography, the definitive diagnoses of stifle lameness because of soft tissue injury have become more common. Likewise, surgical diagnosis and treatment by way of arthroscopy has become routine in most referral centers.

This chapter includes functional anatomy and diagnostic techniques pertaining to this complex joint in the horse, followed by disorders of the stifle joint, which have been divided into traumatic and developmental categories.

FUNCTIONAL ANATOMY

The stifle consists of two joints—the femoropatellar and the femorotibial5 (Fig. 101-1). The femoropatellar joint has a large suprapatellar pouch, and the joint capsule inserts abaxially on the trochlear ridges, forming a lateral and a large medial cul-de-sac on each side. The femorotibial joint consists of two separate synovial sacs that do not communicate.5,6 Each synovial sac is divided into a cranial pouch and a caudal pouch by the condyles (Fig. 101-2). The volume in the medial and lateral synovial cavities of the femorotibial joints is reported to take, respectively, 41.67 ± 5.77 mL and 61.67 ± 2.89 mL of fluid injection. The cruciate ligaments are situated between the two synovial cavities of the femorotibial joint.
There is communication between the femoropatellar joint and the medial femorotibial sac that is rarely absent, but the communication between the femoropatellar joint and the lateral sac of the femorotibial joint occurs in only 18% to 25% of horses.\(^5,9\) In experimental studies, the communication between the femoropatellar joint and the medial sac of the femorotibial joint was found to be 60% to 65% and 1% to 17.5% between the femoropatellar joint and the lateral sac of the femorotibial joint.

**DIAGNOSTIC TECHNIQUES**

**Inspection**

Lameness evaluation of the stifle includes observation of the horse both at rest and during movement, palpation of the synovial structures of the joint and the patellar ligaments, and diagnostic aids such as manipulative tests and intra-articular anesthesia. Clinical signs depend on the severity and chronicity of the injury. Injuries causing pain such as fractures, sepsis, or instability of the joint (cruciate or collateral ligament damage) produce the most severe lameness. Chronic lameness of a rear limb results in atrophy of the gluteal muscles, causing an asymmetric appearance of the croup when viewed from the rear. The asymmetry is also exacerbated because the lame horse bears the weight on the affected limb for a shorter amount of time during movement. This results in a shortened anterior phase of the stride when viewed from the side. When viewed from the rear at the trot, there is a greater excursion (vertical displacement) of the tuber coxae on the affected than on the opposite side.\(^10\)

Synovial distention of the femoropatellar joint may be visually obvious (Fig. 101-3) or quite subtle. Subtle changes can be detected by careful palpation between the patellar ligaments and over the patella and by comparing the two stifle joints. Synovial distention of the femorotibial joint sacs can be difficult to detect but can be palpated immediately cranial or caudal to the collateral ligaments. Palpation of swelling or crepitation of the patella indicates patellar fractures. Patellar ligament laxity is difficult to detect by palpation, but if manipulation of the patella proximad and laterad causes pain or the inability to flex the stifle, upward fixation of the patella should be suspected.

**Manipulation**

Manipulative tests of the joint can exacerbate the lameness. These tests include the hock/stifle flexion test, the patellar test, the cruciate test, and an evaluation of the collateral ligaments.

Hock flexion also causes flexion of the stifle and is performed by grasping the distal metatarsus and holding the hindlimb in flexion for 1 to 2 minutes. The fetlock and phalangeal joints are only passively flexed by this method. A positive response to this test causes increased lameness but is not specific for either joint; therefore, one must differentiate by other diagnostic aids.

Two tests have been described for evaluation of the cruciate ligaments. These tests are supposed to elicit pain and lameness because of the abnormal movement created between the femur and the tibia if there is damage to the cruciate ligaments. The first test is for only the most cooperative horses. To perform this test, the examiner stands behind the affected limb and firmly grasps the proximal tibia with both hands (Fig. 101-4). If any movement or crepitation is detected when the examiner gives a quick pull backward, the test is said to be positive.\(^11\) The second test is carried out with the examiner standing directly in front of the affected limb, placing the inside hand on the proximal tibia, and grasping and pulling the tail to load the limb while rapidly pushing and releasing the force on the tibia repeatedly 20 to 25 times. The horse is then trotted away to evaluate for increased lameness.

The medial collateral ligaments can be evaluated by elevating the limb off the ground and placing pressure on the lateral aspect of the stifle joint while abducting the distal limb. The lateral collateral ligament can be evaluated by elevating the limb off the ground and pulling the stifle joint laterally while adducting the distal limb.

**Figure 101-3.** Appearance of bilateral femoropatellar effusion. Note the enlargement over both patellar regions.

**Figure 101-4.** Cruciate ligament test used to detect rupture. The shoulder is placed against the back of the limb and the tibia is pulled caudal and released.
Anesthesia
Intra-articular anesthesia is an important diagnostic aid in determining articular involvement. Although local anesthesia diffuses between all stifle compartments about 75% of the time, when performing intra-articular anesthesia of the stifle, three synovial sites should be injected separately to ensure anesthesia of the intended synovial sac.6,7,12

Arthrocentesis of the femoropatellar joint can be performed through either a cranial or a lateral approach. The cranial approach is performed by inserting a 7.5-cm (3-in.) spinal needle between the medial and middle patellar ligaments or between the middle and lateral patellar ligaments and directing it proximally in the trochlear groove under the patella. The lateral approach is performed by inserting a 3.75-cm (1.5-in.) 18-gauge needle into the lateral cul-de-sac of the femoropatellar joint just caudal to the lateral patellar ligament and approximately 6 cm (2.5 in.) proximal to the lateral tibial condyle.13

The approach for the lateral sac of the femorotibial joint is performed by inserting a 3.75-cm 18-gauge needle between the lateral patellar ligament and the tendon of the long digital extensor muscle or between the previous tendon and the lateral collateral ligament above the proximal edge of the meniscus into the joint. The approach for the medial sac of the femorotibial joint is performed by inserting the 18-gauge needle between the medial patellar ligament and the medial collateral ligament above the proximal edge of the meniscus into the joint. The use of an 18-gauge needle and a bleb of local anesthetic in the skin at the insertion point to reduce limb flexion during the procedure reduces the chance of needle bending and breakage.

DIAGNOSTIC IMAGING
Radiography
Four radiographic views are necessary for complete evaluation of the stifle: lateromedial, flexed lateromedial, caudocranial, and caudal 30-degree lateral craniomedial oblique. With the exception of the caudocranial view, these views can be taken with low-output portable equipment. However, for a complete examination, a caudocranial view of the stifle should be included. In mature horses, the x-ray machine will need a minimum output of 90 kV and 20 mA. Rare-earth screens and films are recommended, and a cassette holder should be used because of the amount of radiation necessary to obtain quality films of this large joint.

The lateromedial view highlights osseous irregularities near the insertion of the cranial cruciate ligament (Fig. 101-5). A flexed lateromedial view of the stifle, with the limb lifted and retracted caudally, permits patellar and condylar lesions to be seen more easily. The caudal 30-degree lateral craniomedial oblique view prevents superimposition of the images of the trochlear ridges and condyles of the femur (Fig. 101-6). The x-ray beam should be aligned 10 to 15 degrees proximodistally and 30 degrees caudolaterally to craniomedial. Lateral trochlear ridge lesions are most easily seen with this view.

The caudocranial view is best obtained by angling the x-ray beam 10 to 20 degrees proximodistally and centered on a line bisecting the limb between the semimembranosus and semitendinosus muscles at a level of the distal third of these muscles. This view is best for demonstrating medial condylar cysts and osteoarthritis of the stifle (Fig. 101-7).

One special view that can be taken is a craniodistal craniodistal oblique view (skyline) (Fig. 101-8). This view is used primarily to evaluate the patella, the intertrochanteric groove of the distal femur, and the trochlear ridges. It is most useful in demonstrating patellar fractures. In standing horses, the limb should be held semiflexed and drawn caudal to the horse. The cassette is held horizontally with its caudal edge against the cranial aspect of the tibia. The x-ray beam should be directed perpendicularly to the cassette as much as possible.

The stifle of the horse has six centers of ossification at birth. This makes radiographic assessment of the foal somewhat challenging. A summary of closure of growth plates and ossification sites is as follows: The patella is fully ossified by 4 months of age. The proximal portions of the trochlear ridges show irregular contours and granular subchondral bone opacity, which slowly becomes a smooth, regular subchondral bone outline between 3 and 5 months
of age. The distal femoral physis closes at 24 to 30 months of age. The femoral condyles are smoothly outlined, and any irregularity except in young foals should be interpreted as pathologic. At birth, the center of ossification of the tibial tuberosity (apophysis) is separated from the proximal tibial epiphysis as well as from the proximal tibial metaphysis. The apophyseal epiphyseal physis closes between 9 and 12 months of age, and the apophyseal metaphyseal physis closes at 30 to 36 months. The proximal tibial physis closes at 24 to 30 months of age. The fibula has multiple ossification centers that can remain incomplete throughout the life of the horse.

In adult horses, the trochlear ridges are smoothly curved in outline, but the medial trochlear ridge has a small, flattened area at its junction with the metaphysis of the femur. The medial trochlear ridge appears more prominent proximally and is flatter than the lateral ridge. On a caudocranial view in the adult horse, the patella is seen superimposed on the lateral cortex of the diaphysis of the femur. The medial femoral condyle is rounder than the lateral condyle, and the lateral joint space of the femoral tibial joint is narrower than the medial joint space. On the cranio-proximal to craniodistal oblique view, the medial trochlear ridge is larger than the lateral ridge and is separated from it by a trochlear groove. The patella is approximately triangular, and its medial angle is blunter than the lateral angle.

**Other Imaging Studies**

Scintigraphy, computed tomography, fluoroscopy, and ultrasonography are additional imaging modalities that can be used to diagnose stifle pathology. The techniques used for scintigraphic examination are similar to those for other joint areas, and although its application for diagnosis of equine stifle lameness has been described, it is limited because of expense \(^\text{14}\) (see Chapter 75). Computed tomography has been limited to research related to anatomic studies of the stifle (Fig. 101-9). Likewise, contrast techniques under fluoroscopic guidance have also been used for anatomic studies but are not of practical value in clinical cases (Fig. 101-10). Ultrasonographic examination of the
stifle, however, has been used to delineate injury in superficial structures, such as patellar and collateral ligaments. Sonographic examination of the human knee is a widely established technique. Although ultrasonography is widely used to diagnose specific equine orthopedic conditions, especially tendon injuries, and the ultrasonic anatomy of the metacarpophalangeal, metatarsophalangeal, shoulder, and tarsal joints have been established, ultrasonographic anatomy and pathology of the equine stifle were limited until recently.

Anatomic structures that can be identified include the cranial and medial third of both menisci, femoral and tibial articular cartilage, and tendons and ligaments surrounding the stifle. However, only a small portion of the cruciate ligaments can be imaged. Pathologic conditions that can be identified include intra-articular bone fragments, thickening of the synovial membrane, joint effusion, and meniscal tears. This modality will continue to assume a more prominent role in the diagnosis of stifle problems in the horse in the future. Currently, the definitive method for determining the extent of intraarticular stifle injuries is arthroscopy.

**ARTHROSCOPY**

Diagnostic and surgical arthroscopy of the equine stifle is well established. Arthroscopy is most commonly performed to treat osteochondrosis of this joint, and most of the approaches have been developed based on the multiple locations of this disorder. Arthroscopy is also used routinely to establish a prognosis after traumatic injury that could involve damage to the menisci, cruciate ligaments, meniscal ligaments, and articular cartilage.

Complete arthroscopic examination of the stifle necessitates exploration of six separate synovial compartments. This, however, is rarely done because compartments are usually explored based on clinical and radiographic findings that often localize lesions to one aspect of the stifle. Because the stifle of the horse consists of two joints, the femoropatellar and the femorotibial, they are explored separately.

The femorotibial joint has two synovial sacs (medial and lateral) that do not communicate normally, and each of these synovial sacs can be divided into cranial and caudal pouches. Furthermore, the caudal pouch of the lateral femorotibial joint sac is divided into two separate pouches, proximal and distal, by the popliteal tendon. The following compartments can be explored:

- The cranial pouch of the medial femorotibial joint
- The caudal pouch of the medial femorotibial joint
- The cranial pouch of the lateral femorotibial joint
- The proximal pouch of the caudal pouch of the lateral femorotibial joint
- The distal pouch of the caudal pouch of the lateral femorotibial joint
- The femoropatellar joint.

**Medial Femorotibial Synovial Sac**

All compartments of the femorotibial joints are best approached with the horse in dorsal recumbency and the limb in flexion with the stifle joint at 70 to 90 degrees. Three arthroscopic approaches for diagnosis and surgical treatment of the cranial pouch of the medial femorotibial joint sac have been described. The lateral approach, where the arthroscope portal is located caudal to the lateral patellar ligament, cranial to the long digital extensor tendon, and 2 cm proximal to the tibial spine, is most commonly used.

With a no. 11 blade, the portal is made through the skin and the deep fascia. Using a blunt trocar, the arthroscopic cannula is directed medially to penetrate the synovial membrane in the lateral aspect of the medial femorotibial joint (Fig. 101-11). Using this approach, the instrument portal is placed halfway between the tibial crest and the patella and midway between the medial and middle patellar ligaments. This allows examination of cranial portions of the medial meniscus, the tibial condyle, and the weight-bearing area of the femoral condyle as well as the medial meniscotibial ligament (Fig. 101-12). The caudal cruciate ligament can be seen under the synovial membrane (Fig. 101-13). Occasionally, the tibial attachment of the cranial cruciate ligament is found if the medial septum is disrupted.

Examination of the cranial pouch of the medial femorotibial synovial sac is best accomplished by locating the arthroscope portal 1 cm proximal and parallel to a line drawn from the tibial tuberosity to the medial condyle of the tibia and 3 cm caudal to the medial collateral ligament (Fig. 101-14). The entire caudal aspect of the medial femoral condyle and the proximal aspect of the medial meniscus can be examined (Fig. 101-15). The caudal cruciate ligament is located extrasynovially and can be located with the probe through the synovial lining.

**Lateral Femorotibial Synovial Sac**

The arthroscopic portal for examination of the cranial pouch of the lateral femorotibial joint sac is best located midway between the patella and the tibial crest and halfway...
between the medial and middle patellar ligaments. The arthroscope portal is directed laterally and caudad to enter the lateral joint pouch. The cranial cruciate ligament is seen from this approach lying in the medium septum. The lateral femoral condyle, the lateral meniscus, the lateral meniscotibial ligament, and the lateral tibial condyle can be visualized, but this joint compartment is much smaller than the cranial pouch of the medial femorotibial joint sac, and manipulation of the arthroscope is more limited. The opening into the synovial diverticulum of the long digital extensor tendon within the sulcus muscularis of the tibia can be seen; however, exploration of this compartment distally along the tendon is only accomplished through a cranial approach (see later).

The arthroscope portal that permits best examination of the proximal compartment of the caudal pouch of the lateral femorotibial joint sac is located 2.5 cm proximal and parallel to a line drawn from the tibial tuberosity to the lateral condyle of the tibia and 3 cm caudal to the lateral collateral ligament (see Fig. 101-14). Most of the caudal aspect of the lateral femoral condyle and tendon of the popliteus muscle can be examined intrasynovially. Rotation of the hock laterally (clockwise rotation of the right hindlimb) loosens the popliteal tendon and creates a tunnel. Insertion
of the arthroscope into the tunnel does not permit visualization of the lateral meniscus or of the tibial condyle. This is the most common portal used to approach this compartment.

The arthroscope portal that permits examination of the distal compartment of the caudal pouch of the lateral femorotibial joint sac is located on a line drawn from the tibial tuberosity to the lateral condyle of the tibia and 1.5 cm caudal to the lateral collateral ligament (see Fig. 101-14). Entrance to this level is directly through the popliteal tendon, permitting examination of the caudal lateral meniscus, part of the caudal aspect of the lateral femoral condyle, and the intra-articular portion of the popliteal tendon and the lateral tibial condyle (Fig. 101-16). Care should be taken when approaching the caudal pouch of the lateral femorotibial joint sac to avoid damage to the common peroneal nerve, which is located less than 7 cm caudal to the lateral collateral ligament. Additionally, the popliteal artery and vein are situated directly between the medial and lateral femoral condyles on the caudal aspect of this joint (see Fig. 101-9). Therefore the surgeon cannot pass safely from one pouch to the other across the caudal aspect of the joint without risk of injury to this vasculature, which is the major deep blood supply to the stifle.28

Femoropatellar Joint

Exploration and surgery on the femoropatellar joint are best accomplished with the horse placed in dorsal recumbency and the limb in extension. The portal for the arthroscope is located between the middle and lateral patellar ligaments halfway between the tibial crest and the patella29 (see Fig. 101-11).

The arthroscope sleeve, containing a blunt obturator, is inserted through the small skin incision and directed at an angle of 45 degrees up underneath the patella. The object is to place the sheath and obturator into the trochlear groove. Prior distention of the femoropatellar joint is usually not necessary to accomplish positioning of the arthroscope. The joint is then distended through the arthroscope sleeve, which allows sequential examination of the femoropatellar joint, along the entire lengths of both medial and lateral trochlear ridges, the articulating surface of the patella, and the attachments of both the medial and lateral patellar ligaments onto the patella.

Figure 101-14. Schematic representation of the arthroscopic portals used to explore the caudal pouches of the medial and lateral femorotibial joints. a, The portal to the proximal compartment of the lateral caudal pouch is located at the level of the lateral femoral condyle, 2.5 cm proximal to the distal level of the lateral meniscus and 3 cm caudal to the lateral collateral ligaments. b, The portal to the distal compartment of the lateral caudal pouch is located at the level of the lateral meniscus, through popliteal tendon, 1.5 cm caudal to the lateral collateral ligament. c, The medial portal is located at the level of the medial femoral condyle, 1 cm proximal to the distal level of the medial meniscus and 3 cm caudal to the medial collateral ligament.

Figure 101-15. Arthroscopic view of the caudal pouch of the medial femorotibial joint of the stifle showing the medial femoral condyle (M), the medial meniscus (MM), and a probe placed on the caudal cruciate ligament located behind the synovial membrane.

Figure 101-16. Arthroscopic appearance of the distal compartment of the caudal pouch of the lateral femorotibial joint sac, which permits examination of the caudalateral meniscus (right dorsal), part of the caudal aspect of the lateral femoral condyle (right middle), and the interarticular portion of the popliteal tendon (center).
Instrument portals can be created between the middle and medial patellar ligaments for medial trochlear ridge lesions; portals can be created medial, lateral, or through the lateral patellar ligament for lateral trochlear ridge lesions. The instrument portal is located proximal and lateral to the arthroscope portal when it is passed through the lateral patellar ligament. If the portal is made lateral to the lateral patellar ligament, it is sometimes difficult to manipulate the instrument to operate effectively on lesions in this area.\textsuperscript{30}

**Cranial Arthroscopic Approach to the Cranial Stifle**

An alternative arthroscopic approach for a complete examination of the cranial aspect of the stifle has been described,\textsuperscript{31} wherein the endoscope portal is made through the middle patellar tendon into the femoropatellar joint. Thereafter, each femorotibial joint sac is entered via a cranial incision using arthroscopic hook scissors under arthroscopic guidance. This incision is made through the slit-like openings into the femorotibial joints at the distal end of the medial and lateral trochlear ridges. These are easily identified during routine examination of the femoropatellar joint pouches. Good visualization of the femoral and tibial condyles and the meniscus are obtained. An excellent image of the caudal cruciate ligament enhances evaluation and débridement of this structure.

Modification of this technique by entering the femoropatellar joint on either side of the middle patellar tendon avoids damage to this structure while permitting more mobility of the endoscope.\textsuperscript{32} This technique has the advantage of easier scope placement through one portal, which allows access to the entire cranial aspect of the stifle joints. Single portal entry can decrease morbidity and permits better access to soft tissues of the femorotibial joints. This approach to the cranial stifle is used preferentially by the author and was evaluated in the treatment of 23 horses with various stifle disorders.\textsuperscript{33}

The technique is as follows (Fig. 101-17 and 101-18). The horse is anesthetized and placed into dorsal recumbency, and the stifle joint is maintained in 60 degrees of flexion. An 8 mm long skin incision is made 2 cm medial to the middle patellar ligament and 1 cm distal to the distal end of the patella. The incision is extended through the superficial and deep fascia.

An arthroscopic cannula containing a blunt trocar is advanced through the incision distally and caudally within the femoropatellar joint without prior joint distention. The trocar is replaced by the arthroscope, and placement of the cannula in the joints is verified by observing the articular surface. Sterile polyionic fluids are delivered to distend the joint, and the femoropatellar joint is examined systematically.

The slit-like synovial membrane separating the cranial aspects of the femorotibial joint compartments from the femoropatellar joint are identified medially and laterally overlying the cranial and distal aspects of the femoral trochlea. The instrument entry portal is made into the femoropatellar joint lateral to the middle patellar ligament opposite the arthroscopic portal and at the same level. The instrument portal is placed at the same distance from the distal patellar margin and is of the same size and orientation described for the arthroscopic portal.

Arthroscopic hook scissors (Fig. 101-19) are placed in the femoropatellar joint through this accessory portal. Synovial membrane overlying the medial femoral trochlea is transected with hook scissors (Fig. 101-20), allowing the arthroscope to advance into the medial femorotibial joint compartment (Fig. 101-21).

If indicated, the procedure is repeated using an identical approach to the lateral femorotibial joint compartment. The arthroscope does not need to be removed from its medial position and can be driven into the lateral femorotibial joint compartment after the incision is made with the hook scissors. This allows very good visualization of the cranial aspect of this compartment and also allows exploration of the sulcus muscularis containing the long digital extensor tendon.

The cranial pouches in both femorotibial joint compartments can be successfully evaluated through this single portal cranial arthroscopic approach, which uses the femoropatellar joint as a point of access. Arthroscopic placement is critical to obtain optimal entry into the femorotibial joint. The arthroscope is positioned 1 cm distal to the palpable distal end of the patella. The view of the synovial membranes present over the trochlear ridges will be distorted or inaccessible if the arthroscope portal is located farther distally, as occurs with a traditional approach to the femoropatellar joint previously described.
Using the hook scissors through a portal placed too far distal is awkward because of the acute angle formed between the synovial membrane and the instrument. Hook scissors are not effective despite correct instrument portal placement when the synovial membrane is thickened. This is particularly obvious in horses with chronic joint disease in which fibrous synovial membranes have to be transected with a scalpel blade inserted through the instrument portal. After incision, however, access to this joint is excellent. Directional movements of the arthroscope and examination of synovial structures within the femorotibial joint compartments will be facilitated once the synovial membrane located between the joints is transected.

Arthroscopic assistance of the cranial approach permits a controlled and atraumatic injury into the femorotibial joint compartments, thereby decreasing the reported risk of inadvertent meniscal damage from blind trocar insertion penetrating articular structures. This is particularly true when entering the lateral femorotibial joint compartment because a blind direct approach is complicated by the presence of the lateral collateral ligament, the lateral patellar ligament, and the origin of the long digital extensor tendon. Additionally, the controlled insertion eliminates the risk of extravasation of fluid in the periarticular tissues, which causes edema and renders the surgical approach difficult.

A unique feature of the single portal cranial arthroscopic approach to the stifle in horses is that a communication is created between the femoropatellar and femorotibial joints. Synovial fluid of all joint pouches freely communicates, and when joint lavage is performed at the completion of surgery it involves all compartments. When curetting medial femoral condylar cysts (see later) using this technique, it is important to remember that the suprapatellar pouch is explored before exiting the joint with the arthroscope. Some
care should be taken not to allow a lot of debris to fall into the femorotibial joint because it can be difficult to extirpate from the cul-de-sacs of the suprapatellar pouch.

There are a few disadvantages to the cranial approach. These include the need for an additional instrument (hook scissors) and the learning period associated with mastering a new technique. Furthermore, the cranial approach might not lend itself to the evaluation of septic arthritis of the stifle joint. In horses that have only a single infected compartment, care should be taken not to contaminate other healthy synovial structures. However, because 70% of the time the medial femorotibial joint and the femoropatellar joint communicate, this might not be an issue, and the cranial arthroscopic approach can be used.

Because the cranial arthroscopic approach eliminates the natural synovial barriers between both compartments, joint sepsis can be advantageously treated by vigorous joint lavage through a large opening created within the cranial arthroscopic approach. This is particularly important if the sepsis is in the lateral femorotibial joint compartment and involves the sulcus muscularis.

In summary, the cranial arthroscopic single portal approach is easy to perform, allows controlled access to the femorotibial joint, avoids accidental damage to articular structures, and requires fewer access portals to explore the entire cranial aspect of the stifle.

**DISORDERS OF THE STIFLE**

**Traumatic Disorders**

Acute or chronic traumatic conditions of the stifle include osteoarthritis, synovitis, chondromalacia of the patella, meniscal tears, ligamentous disorders (e.g., sprains, avulsions, tears), and fractures. All of these disorders can exhibit the signs of gonitis, with joint distention and lameness.

**Osteoarthritis**

The earliest form of osteoarthritis in the equine stifle is recognized as cartilage damage on the medial femoral condyle, which results secondary to joint injury. These lesions produce lameness in the horse, and diagnostic arthroscopy is necessary to make an accurate diagnosis. Therefore, horses with lameness localized to the stifle through diagnostic anesthesia or scintigraphy and in which radiography and ultrasonography did not yield a diagnosis are good candidates for arthroscopic exploration of the joint. Débridement of focal cartilage lesions allows some horses to successfully resume performance activities.

Osteoarthritis of the stifle in later stages is best detected on a craniocaudal radiographic view when the femorotibial joint is involved and manifests as articular osteophyte formation, flattening of the articular surfaces, sclerosis of the subchondral bone, or lucent zones in the subchondral bone. Narrowing of the femorotibial joint space is seen in advanced cases. Positioning is important when making this determination; the horse should be bearing weight, with the limb centered under the body during this view. The lateromedial view demonstrates femoropatellar joint osteoarthritis, which is seen as periarticular osteophyte formation and changes along the distal aspect of the patella. Treatment for this condition is usually palliative, as with all other arthritic conditions, and includes intra-articular medications. Because of the size of these synovial compartments (with a volume of between 40 and 62 mL), intra-articular medications must be of sufficient quantity to be effective.

Osteoarthritis is usually established in the femorotibial joints as a result of some meniscal or ligamentous injury; however, advanced cases of osteoarthritis with complete denuding of articular cartilage from the medial femoral condyle can be seen in aged racing Standardbreds without evidence of other soft tissue injury. Treatment of this condition by way of arthroscopy can include articular cartilage débridement and micropick techniques.

Pannus formation of the femorotibial and femoropatellar joint compartments can be treated with anti-inflammatory medication, but may best respond to arthroscopic débridement of synovial proliferation. If the surgeon is exploring a joint in which this is the only finding, mechanical débridement by way of mechanical synovial resectors or a holmium:yttrium-aluminum-garnet (holmium-YAG) laser is indicated.

Articular cartilage lesions on the surface of the patella are called chondromalacia. The pathogenesis and significance of this condition in the horse are uncertain, but arthroscopic débridement of cartilage fragmentation using minimally traumatizing motorized cartilaginous débriders has resulted in clinical improvement.

**Ligamentous Disorders**

In addition to collateral ligaments common to most joints, the stifle of the horse includes ligaments associated with the menisci, cranial and caudal cruciate ligaments, and three
patellar ligaments. All ligaments are subject to sprains, strains, and tears.

UPWARD FIXATION OF THE PATELLA
Upward fixation of the patella is a condition that is unique to the horse. It is believed that this condition occurs secondary to the beginning of training in young horses and is related to a straight hindlimb conformation.

Training
The treatment for this condition involves alterations in training rather than surgical treatment. As a treatment for this condition, medial patellar desmotomy has been associated with induction of chondromalacia of the patella and patellar fragmentation. If this occurs, these fragments should be removed arthroscopically because they will lead to osteoarthritis. Except in Shetland ponies and miniature horses (horses that would not be expected to carry a rider), the treatment for this condition involves developing quadriceps muscle tone.

Quadriceps development is accomplished by riding at an extended trot up and down hills in deep, sandy, or loamy soil. Working the horse in a circle in an arena (and especially at a canter) should be avoided. This merely contributes to the trauma to the patella and the horse’s continued lack of quadriceps development because of lameness. Rather than box stall confinement, anti-inflammatory medication and turnout for the horse are recommended.

Medial patellar desmotomy
If the appropriate conditioning and development of the quadriceps muscle tone with training does not resolve the condition, medial patellar desmotomy can be considered as a last resort in riding horses.

The surgical procedure is performed with the animal standing and the tail wrapped to avoid contamination of the surgical site. After preparation of the skin, local anesthetic is injected subcutaneously over the medial border of the middle patellar ligament. A 20-gauge 2.5-cm (1-inch) needle is inserted through this site, and the subcutaneous area around the distal part of the medial patellar ligament is infiltrated with local anesthetic.

A 1-cm incision is made over the medial border of the middle patellar ligament close to the attachment of the ligament to the tibial tuberosity. This is done because a fat pad is located in this area and the operator is less likely to enter the femoropatellar joint capsule at this site. Curved Kelly forceps are forced through the fascia and passed beneath the medial patellar ligament. A curved bistoury knife is inserted into this channel, the cutting edge is turned outward, and the ligament is cut. The blade should be placed completely on the other side of the medial patellar ligament before the ligament is severed. Once the ligament has been severed, the tendon of the sartorius muscle feels like a tense band and might lead the inexperienced operator to believe that the medial patellar ligament has not been completely severed. The skin is closed.

To avoid the complications discussed above, a prolonged period of rest is important before the animal is turned out to...
allow some scarring to occur at the surgery site, realigning the patella in the intertrochanteric groove.

**Medial patellar ligament splitting**
Medial patellar ligament splitting has been advocated for treating upward fixation of the patella when conservative methods have failed. The authors claim numerous advantages over medial patellar desmotomy. The procedure is carried out under general anesthesia.

Using ultrasonographic guidance, multiple longitudinal splitting incisions are made in the distal aspects of the medial patellar ligament. This form of splitting results in a significant progressive increase in ligament size during the first 4 weeks after surgery. The final result is that the medial patellar ligament becomes thickened two to three times its initial diameter.

**TEARING OF COLLATERAL LIGAMENTS**
Collateral ligaments of the femorotibial joint can undergo partial tearing. A diagnosis is made in acute cases with ultrasonography. Radiographs can be obtained with the joint under lateral or medial stress to confirm unilateral widening of the femorotibial joint space when complete rupture is suspected. Sprain of these ligaments can result in increased irregular new bone formation, which manifests as enthesiophyte formation at the insertions on the proximal tibia.

Treatment for this condition involves anti-inflammatory medication and rest. Healing should be monitored by periodic ultrasonographic examinations. The prognosis for horses undergoing partial tearing is guarded to favorable, depending on the degree of tearing and instability of the joint.

Concurrent injury of the menisci or cruciate ligaments commonly occurs in horses with severe injuries or complete rupture of a collateral ligament. The medial collateral ligament and medial menisci are more commonly involved than the lateral aspect of the stifle. When concurrent structures such as the cruciate ligaments or menisci are involved, the prognosis is unfavorable for full return to athletic use.

**RUPTURE OF THE CRUCIATE LIGAMENT**
Complete rupture of the cranial cruciate ligament, or less commonly the caudal cruciate ligament, has been reported and carries an unfavorable prognosis for the horse’s return to athletic function. Weightbearing might return over time, but often extensive osteoarthritis prohibits even salvage of the horse as a breeding animal.

Much more commonly, sprain of the cruciate ligaments, with or without partial detachment of their distal insertions, occurs. Occasionally, avulsion of the tibial crest occurs or enthesiophytes develop in the ligament and can be seen on radiographs (see Fig. 101-5). Chronic cases can have proliferative bone changes, which can be seen in the flexed lateromedial view. Subchondral cystic lesions can develop at the sites of origin and insertion of the cruciate ligaments over time.

A definitive diagnosis is made after an arthroscopic examination of the femorotibial joint (Fig. 101-26). A lateral approach to the medial compartment has been used, and the septum between the two cranial compartments will have been ruptured with the traumatic injury, allowing examination of both cruciate ligaments through this approach. However, the cranial approach to both femorotibial joints permits more complete assessment. Treatment involves partial débridement. The prognosis is related to the amount of damage to the cruciate ligament.

The majority of horses with minor superficial cranial cruciate tearing (Fig. 101-27) return to previous degrees of activity and can be used without further lameness. When the damage becomes moderate and approaches disruption of more than 50% of the ligament, the prognosis is unfavorable. Concurrent meniscal injury worsens the prognosis.

**Meniscal Injury**
Meniscal tears in the equine femorotibial joint have been recognized for more than a decade. Continued improvements in arthroscopic and ultrasonographic techniques have...
led to an increase in this diagnosis. Although lameness is often acute and severe in onset after a traumatic incident in which the meniscal injury occurs, it usually becomes low grade and persistent after a period of time. The medial meniscus is involved 75% of the time and the cranial meniscotibial ligament of the menisci is almost always involved.

Distention of the joints can be expected in some horses; however, the most diagnostic clinical sign is severe lameness following the hindlimb flexion test. Traumatic injuries severe enough to cause damage to the menisci are usually the result of damage to other major structures such as the collateral ligaments, the meniscal ligaments, or the cruciate ligaments. The diagnosis is made on arthroscopic assessment of the femorotibial joint compartments (Fig. 101-28). The medial meniscus is seen with a lateral or cranial approach to the cranial pouch of the medial femorotibial joint sac. However, lateral meniscal tears are less common and can be seen best through an approach to the caudal pouch. Treatment is by way of resection of the torn portion of the menisci using motorized meniscal resectors.

Because only the cranial and caudal poles of the menisci can be seen, arthroscopic assessment of meniscal injury is incomplete. A grading system has been established to determine prognosis as a meniscal tear is examined in the cranial pouch of the femorotibial joint:

Grade 1: Tears extending longitudinally from the cranial ligament into the meniscus with minimal separation (Fig. 101-29)
Grade 2: Tears involving the cranial pole in which the extent of the injury is visible
Grade 3: Severe tears that extend beneath the femoral condyle and that cannot be completely assessed or debrided (see Fig. 101-28)

It has been reported that return to full athletic use can be expected in about 50% of horses overall. However, the best prognosis is in horses with lower grades of meniscal tears because only 25% of horses with grade 3 tears can be returned to athletic use. Concurrent damage to the cruciate ligament worsens the prognosis.

**Fractures**

**PATELLA**
The patella is the largest sesamoid bone in the body and an integral portion of the quadriceps apparatus. Fractures of the patella are occasionally diagnosed and usually result from some direct trauma. These fractures cause variable lameness, soft tissue swelling, and effusion depending on the amount and configuration of the fracture. Radiographic evaluation should include not only the craniocaudal, lateromedial, flexed lateromedial, and caudal 30-degree lateral craniomedial oblique views but also the cranioproximal craniodistal (skyline) view of the patella to make a complete assessment of the fracture. Patellar fracture morphology is highly variable; however, sagittal fractures are most common and usually involve the medial aspect of the patella (see Fig. 101-8).

Techniques for partial patellectomy and internal fixation have been described; however, fractures located at the base...
of the patella are rarely emergencies and do not normally require surgical intervention (Fig. 101-30). Surgery should be attempted only if the fracture gap is greater than 5 mm on radiographs, there is obvious malalignment of an articular fragment, or fragments can be palpated under the skin. One should allow for the swelling to decrease before surgical intervention is attempted. Medical management should include administration of nonsteroidal anti-inflammatory drugs for 2 weeks and stall confinement for 2 to 3 months.

Figure 101-30. Lateromedial radiographic view of the stifle showing a fracture at the base of the patella.

Only when there is disruption of the quadriceps apparatus or a very large displaced articular fragment is internal fixation indicated (Fig. 101-31). Repairs have been performed through arthrotomy into the femoropatellar joint, and lag screw fixation using two or three 5.5-mm cortex screws placed from the apex to the base has been described. Partial patellectomy is indicated in sagittal medial articular fractures.49,50 This can be carried out by removing up to one third of the patella through arthroscopy. A mechanical resector is used on the fragment to create a separation between the fragment and the parent portion of the bone. With an osteotome, the fragment is divided into smaller fragments, which subsequently are removed with Ferris-Smith rongeurs. However, it is often necessary to perform an arthrotomy, because dissection of the fragment from its extensive patellar ligament attachment can be difficult using only arthroscopic techniques. The prognosis after partial patellectomy for sagittal transverse fractures is favorable. When the quadriceps apparatus has been disrupted, the prognosis is guarded to unfavorable, depending on the success of the repair.

FEMORAL TROCHELEAR RIDGES
Fractures of the femoral trochelear ridges usually result from external trauma or wounds to the stifle. Either trochelear ridge can suffer fragmentation.51 Clinical signs include sudden onset of moderate to severe lameness and effusion of the femoropatellar joint. Crepitus may be present on flexion of the joint. The fracture site might not be obvious unless a wound is present; however, the risk of sepsis is present when a skin wound is observed.

Figure 101-31. A, A lateromedial radiographic view of a patella fracture that resulted in complete disruption of the quadriceps apparatus. B, One 5.5-mm cortex screw used in lag fashion and two dynamic compression plates (DCPs) were used in the repair.
Fracture fragments should be removed. This is usually possible arthroscopically. Trochlear ridge fractures have a good prognosis after fracture removal, if no significant deeper structures are involved in the injury. Because of the non-weight-bearing articular surface where this usually occurs, horses can usually return to complete athletic activity.

_Avulsion of the Origin of the Peroneus Tertius and Long Digital Extensor Tendon_

This unusual condition in horses is commonly caused by a sudden forceful hyperextension of the hindlimb. Although mid-body tears of these structures are more common, usually from the horse lodging its foot in a gate and then forcibly extracting it, avulsions of the origin of the peroneus tertius and long digital extensor muscle do not have to occur with entrapment of the distal limb. Foals are most likely to suffer these avulsions, whereas the body of the structure tears in adult horses.52

Clinical signs are similar to those found with rupture of the peroneus tertius (see Chapters 86 and 99). However, distention of the femorotibial and femoropatellar joints is a cardinal sign that more might be involved than simply rupture. The condition can be recognized radiographically (Fig. 101-32).

Treatment is usually initiated by arthroscopic evaluation, which offers the opportunity to check the stifle for concurrent injury. Arthroscopy of the lateral femorotibial joint sac via a cranial approach can be used. The subchondral bone in the area of the extensor fossa and origin of the long digital extensor tendon can be débrided and bone fragments removed. Prognosis following this injury is guarded because many horses continue with some lameness following this injury.52,53

**Developmental Disorders**

**Osteochondrosis**

Osteochondrosis (OC) is a term used to describe the developmental cartilaginous disease where failure of endochondral ossification results in thickening of the metaphyseal growth plate or the articular cartilage.54,55 The etiopathogenesis of osteochondrosis and subchondral cystic lesions are discussed in detail in Chapters 91 and 92. For the purpose of discussion in this chapter, OC lesions have been divided into two categories: osteochondritis dissecans, which occurs as osteochondral fragments, and subchondral cystic lesions, seen as bone cysts.

**OSTEOCHONDritis DISSECANS**

Osteochondritis dissecans (OCD) is the most common cause of lameness in the stifle, and the femoropatellar joint is one of the principal sites in the horse.56 The primary area involved is the lateral trochlear ridge of the femur (Fig. 101-33). The medial trochlear ridge, the patella, and the trochlear groove are involved less often.56 Bilateral involvement is common. OCD has been reported in many breeds, but the Thoroughbreds, Quarter Horses, Arabians, and Warmbloods are over-represented. Most of the horses affected with OCD are between 1 and 2 years of age, but OCD has also been reported in very young horses.

![Figure 101-32. Lateromedial view of the stifle in a foal showing avulsion of the femoral insertion of the peroneus tertius and long digital extensor tendon.](image)

![Figure 101-33. Arthroscopic appearance of osteochondritis dissecans of the lateral trochlear ridge demonstrating an osteochondral flap and an adjacent kissing lesion at the lateral aspect of the patella. a, lateral trochlear ridge of the distal femur; b, patella; c, OCD flap.](image)
Radiographic examination of Thoroughbreds at the time of the yearling sales has become a common part of the selection process. This has allowed the prevalence of osteochondrosis of the stifle to be determined in a large group of Thoroughbred yearlings presented for sale. The most common osteochondrosis lesion observed is flattening or fragmentation of the lateral trochlear ridge of the femur (6% of 660 horses). This has a significant effect on future racing performance, and therefore stifle OCD is a detrimental finding in this breed.

Affected horses can be presented with acute, severe lameness or with a subtle lameness that becomes more obvious with increasing exercise. Varying degrees of synovial effusion and lameness depend on the severity of the lesions. Young horses and horses that show clinical signs before training usually have more severe lesions from OCD than do those that do not show clinical signs until after training is initiated. In very young horses, the disease can be so severe as to cause difficulty in rising. Flexion test of the stifle usually increases the lameness.

A radiographic examination confirms the diagnosis, and the most common lesions are seen as flattening and irregularity of the trochlear ridge. This should not be confused with the irregularity of subchondral ossification of the trochlear ridges in foals younger than 5 months of age. Smooth subchondral bone concavities, subchondral bone lysis, and osteochondral flaps and fragments are other lesions that are seen less often. Radiographs usually underestimate the severity and the extent of the lesions, especially in foals younger than 9 months of age. Therefore, if signs of stifle OCD are present (femoropatellar distention and lameness), arthroscopic treatment might need to be delayed until radiographic signs are obvious. During this time, these lesions have been observed to heal, with resolution of signs reported in young foals (see Chapter 91).

The treatment of choice for OCD is arthroscopic removal of osteochondral fragments and loose and undermined cartilage and débridement of the subchondral bone lesion. Surgical success rates of approximately 64% without regard to sex, use, location of lesions, or bilateral or unilateral involvement have been reported. Conservative management of OCD has yielded poor results but might be appropriate under certain circumstances. In one study, early detection and rest allowed lesions to heal and approximately 50% of horses were able to race; however, these animals tended to have less-severe lesions and no joint fragmentation.

**MEDIAL FEMORAL CONDYLAR CYSTS**

Subchondral bone cysts (SBCs) of the medial femoral condyle are an important and common cause of hindlimb lameness in the horse. There are two commonly proposed causes: articular damage with mechanical trauma of the subchondral bone and developmental orthopedic disease in the form of osteochondrosis. In support of the former theory, SBCs can be induced experimentally by creating a defect in the subchondral bone of the medial femoral condyle (see Chapter 92).

Medial condylar cysts develop unilaterally in most cases but can be bilateral on presentation. Usually the medial femoral condyle is affected, but cysts have been described in the lateral condyle and proximal tibia. The age of horses affected with cysts range from a few months up to 15 years of age, but most of the horses are between 1 and 3 years of age.

Lameness is the primary clinical sign and is usually obvious at the trot in one or both limbs. Flexion tests of the stifle can increase the lameness, but the change is usually not dramatic. The condition is usually observed as a stiffness in the limb or a reluctance to flex the limb at a walk or trot, and circling the horse in a trot toward the affected limb can increase the lameness.

Synovial distention is usually difficult to detect, especially in the medial femorotibial joint sac, but it is noticed occasionally in the femoropatellar joint. The condition responds to intra-articular anesthesia, but radiographic examination provides a definitive diagnosis (see Fig. 101-7). Caudal to cranial and lateral to medial projections are important, but the former gives the best detail to the nature of the SBC. Radiographs of both limbs should be taken to detect bilateral lesions. The size of the lesions on the radiographs can vary from a slight indentation in the subchondral joint surface to a very round or oval lesion a few centimeters in height and width. There is usually a communication of the cyst with the joint that can range from being very narrow to quite broad. The size of the lesion and the amount of articular cartilage involvement has been suggested to correlate with clinical signs and prognosis, but this finding has not been confirmed in all studies.

Recommendations for treatment involve arthroscopic surgery for débridement of the lesion followed by injection of betamethasone into the cyst. Débridement of the cyst lining and removal of all debris from the joint is the goal (Fig. 101-34). Compact cancellous bone grafting and press-fit corticocancellous grafts or artificial cartilage implants have not produced an improved outcome. However, novel bone replacement constructs are currently under evaluation, and early results are promising (see Chapter 92).

Postoperative intra-lesional corticosteroid therapy has been advocated to depress the anti-inflammatory mediators that are secreted from the lining in the cyst. Subchondral bone osteostixis is contraindicated because it can worsen the lesion. Additionally, débridement of small condylar defects that are asymptomatic is probably contraindicated because it can provoke an enlargement of the cyst. Therefore, these are quite often treated by intralesional injection of a corticosteroid using arthroscopic guidance.

The success rate for the horse’s return to previous function after surgery ranges from 56% to 72%. Reports on conservative management of this condition, with or without the use of nonsteroidal anti-inflammatory medication, have been reported to be 64%.

**Lateral Luxation of the Patella**

Lateral luxation of the patella in foals is uncommon, is usually congenital, and can be inherited. Luxations of the patella do occur in mature horses but are the result of trauma.

The condition can be unilateral or bilateral, and clinical signs depend on the severity of the displacement of the patella. Foals with complete luxation of the patellas are
unable to stand (because the quadriceps acts as a flexor instead of an extensor of the joint) and assume a classic crouched position (Fig. 101-35, A). When patellas are not completelyluxated, clinical signs include limb stiffness or lameness at the walk and trot. The patellas can usually be reduced manually. The femoropatellar joint is usually distended, and there may be crepitation on palpation of the patella.

Radiographic assessment of the stifle should include the degree of degeneration of the joint, the depth of the trochlear groove, the shape of the patella and trochlear ridges, and the amount of ossification of the trochlear ridges. (Pathology should not be confused with the irregularity of subchondral ossification of the trochlear ridges of foals up to 5 months.) On craniocaudal radiographic views, the patella is located lateral to the femur (Fig. 101-35, B); on the lateromedial view, it is projected over the femur or visible just caudal to it.

Surgical correction of patellar luxations includes lateral release incisions of the patellas combined with reinforcement of the medial patellar structures. In dorsal recumbency, under general anesthesia, surgical exposure is achieved with one large medially based curved incision extending from 6 cm above the patella distally to the tibial crest. Alternatively, two curved incisions can be used.

Lateral release of the patella is accomplished by incising the insertion of the biceps femoris, the lateral femoropatellar ligament, and the origin of the lateral patellar ligament without invading the joint. The lateral release can sometimes be accomplished by partially transecting the tensor fascia and fibrous joint capsule while preserving the lateral femoropatellar ligament. The medial joint capsule from the base to the apex of the patella is imbricated with no. 5 braided polyester suture. Alternatively, suturing the tendon of the sartorius muscle and the parapatellar fascia to the joint capsule and the medial patellar ligament will be necessary. (The author has used a mesh implant to reinforce this imbrication in a 370-pound yearling.)

A sulcoplasty has been advocated for lateral ridge hypoplasia or instability of the patella in the trochlear groove. In small animals, two different techniques are proposed. These techniques are performed on young animals that have a thick hyaline cartilage layer covering the ossifying center of the epiphysis. One technique involves elevation of a U-shaped cartilage flap within the trochlear groove and removal of the subchondral bone (Fig. 101-36). The cartilage is incised at an angle, followed by careful elevation with the help of a periosteal elevator. The soft
bone is removed with rongeurs, and the surface is evened out with a curet. The cartilage flap is then repositioned and stabilized with sutures. If an abrupt change in trough angle on each side is noticed, additional cartilage can be removed with a scalpel to provide a smooth surface.

The other technique involves the removal of a wedge from the trochlear groove (Fig. 101-37) with a hand-held saw. Each saw cut removes some bone. By reapplying the wedge, some deepening of the groove is achieved. If additional deepening is desired, a parallel saw cut is carried out on one side, followed by replacement of the wedge. The edges are smoothed out. If the wedge is properly seated, no fixation is required. The soft tissue release and imbrication techniques discussed earlier are also performed.

Both procedures have been used successfully on foals. Postoperative care includes the use of systemic antibiotics, nonsteroidal anti-inflammatory medication, and good nursing care. Seromas do occur but resolve without treatment. Postoperative radiographs reveal correct positioning of the patella.

FRACTURES OF THE FEMUR

Fractures of the femur occur primarily in foals and weanlings, although they can be found in a horse at any age. Most fractures follow a severe traumatic event, such as a fall or a kick.

The diagnosis is not difficult to make in most cases because of the acute onset as well as the marked lameness and swelling that localize the problem. Although crepitus is usually palpable with manipulation of the limb, hemorrhage and muscle swelling can be severe enough to separate the bone ends and minimize this sign. More severely comminuted fractures might not have crepitus, because motion between the individual fragments is limited. Less common presentations include shock caused by blood loss into the thigh musculature and dragging of the limb because of upward fixation of the patella.

Radiographs in any horse larger than a foal require general anesthesia unless the fracture is located distally. Alternatively, ultrasonography can be used to confirm a diagnosis of a displaced fracture.

Surgical treatment of mid-diaphyseal or proximal femoral fractures has generally been successful only in foals and small ponies. Distal metaphyseal fractures can also be successfully repaired in yearlings with plates and screws. Locking intramedullary nails are an option for mid-diaphyseal fractures in foals and even larger yearlings.

Proximal (Head and Neck) Fractures

Proximal (head and neck) fractures are seen almost exclusively in foals and are the most difficult femoral fractures to diagnose without good-quality radiographs. Conservative treatment of such fractures is unlikely to result in a comfortable horse. Surgical repair is difficult to achieve, and the prognosis is guarded.

The favored surgical approach is craniodorsal, with a curved incision just cranial to the greater trochanter and that parallels the proximal shaft of the femur. Exposure is enhanced by either a tenotomy of the gluteal insertion or a trochanteric osteotomy. If an osteotomy is selected, the drill holes for later tension-band repair should be prepared before transecting the bone.

The bone can be cut with an oscillating saw or Gigli wire. The approach and arthrotomy are extended to allow palpation of the head and neck of the femur. Additional fractures that are not evident radiographically are detected in this manner. It is usually impossible to see the fracture site, but having fingers in the joint allows more accurate reduction of the fracture and alignment of the drill bit.

Although use of multiple pins has been described, techniques involving screws provide more stability. These techniques include screws applied in lag fashion, cannulated screws, or a dynamic hip screw plate. Regardless of the specific implant selected, alignment is critical to prevent damage to the articular surface. Cannulated screws have a major technical advantage for this particular fracture, because reduction is maintained by the guide wire during the entire procedure and the direction and depth of the drill or screw can be monitored constantly (see Chapter 81). Cannulated screws are significantly weaker in bending than solid screws, so there is a risk of screw failure in larger foals.

If a cortex screw and lag technique are used, the glide hole is drilled before reduction. This makes it possible to check for central positioning of the bit before entering the epiphysis with the thread hole. This central location maximizes the number of threads engaged in the small fragment. If the screw is not centered in the epiphysis or the epiphyseal fragment is penetrated off center with the large bit used for the glide hole, stability of the repair will be compromised.

Ease of reduction is variable and depends mainly on the degree of eburnation of the fracture surfaces. Smooth, eburnated fracture margins make reduction difficult. If the femoral shaft is held with forceps, leverage is provided when attempting reduction. However, reduction is maintained digitally because clamps cannot be applied. Predrilling the glide hole across the femoral shaft also minimizes the length of time that the fracture must be digitally maintained in reduction.

It is difficult to accurately estimate the ideal length of screw from preoperative radiographs; thus, intraoperative palpation and measurements are essential. To assess the depth and direction of drilling, a pin or drill bit of the same length is placed on the exterior of the bone in a parallel position as drilling is performed. This provides additional visual and tactile help for alignment as holes are drilled into the head of the femur. If at all possible, two screws should be used to ensure rotational stability.

FRACTURES OF THE FEMUR
